Abstract

AI has supported nursing and health care for years through decision support, prediction, monitoring, and workflow tools; what is changing is the breadth and proximity of AI-generated information to everyday care. Existing nursing AI literature has advanced AI literacy, safety, ethics, and governance, yet less attention has focused on how AI-mediated care reshapes contextual nursing judgment, patient recognition, professional behavior, and relational accountability at the point of care. Nursing digital competence may therefore increasingly need to extend beyond AI literacy toward humanistic meaning-making and behavioral governance. We offer MESH as a provisional integrative nursing lens with 4 domains: meaning-making, ethical presence, system and relational workflow governance, and human-in-the-relationship. Standardized nursing data are considered one enabling bridge through which nursing-sensitive information may remain visible within AI-supported decision environments. The MESH-action cycle—recognize, interpret, communicate, govern, and evaluate—is proposed as a 5-step practice-oriented pathway for applying these domains. MESH is not a validated competency model; its purpose is to support inquiry, education, implementation design, and empirical testing of whether AI augments or obscures nursing judgment and patient recognition.

artificial intelligence; AI; nursing; digital health; nursing informatics; humanistic care; clinical judgment; behavioral governance; AI-mediated care; nursing leadership; patient recognition

Introduction: AI and the Expanding Interpretive Space of Care

AI is not new to nursing or health care. Rule-based clinical decision support, automated classification, predictive models, and monitoring systems have influenced clinical work for years [1-5]. What is changing is the scope and proximity of machine-generated information to everyday care. Predictive and other AI-based technologies are increasingly used across clinical and operational functions [1,6], while generative and conversational systems can synthesize narratives, generate text, and participate more directly in clinician-patient communication [7]. AI therefore does more than add another tool to clinical workflows; it can participate in the informational and interpretive processes through which clinicians understand patients and determine care priorities.

These capabilities may improve safety, efficiency, access, and information synthesis. At the same time, as AI-enabled clinical information systems summarize, classify, and prioritize clinical information, the representation of the patient can become progressively abstracted. This raises a deeper nursing question: can care become more efficiently processed while the patient feels less personally recognized [8-10]? The concern is not limited to technical error, algorithmic bias, or inadequate literacy. It also concerns how machine-generated representations influence nursing attention, interpretation, communication, and accountability.

AI-mediated nursing care refers here to clinical situations in which AI-generated classifications, predictions, summaries, recommendations, or communications materially shape how patient information is represented, interpreted, communicated, prioritized, or acted upon within nursing workflows. It should therefore not be understood only as the use of AI tools in nursing practice. This viewpoint examines how nursing judgment, patient recognition, nursing-data visibility, professional behavior, and workflow governance interact under such conditions and proposes meaning-making, ethical presence, system and relational workflow governance, and human-in-the-relationship (MESH) as an integrative nursing lens for that interaction.

Why AI Literacy Is Necessary but Insufficient

Recent nursing AI scholarship has advanced essential conversations across several complementary areas. AI literacy

XSL•FO
RenderX

and competency work has clarified knowledge, verification, responsible use, and the capabilities nurses may need when working with AI [6,11-13]. Nursing leadership and governance scholarship has addressed implementation, sociotechnical safety, accountability, and organizational readiness [1,11,14-16]. Nursing ethics literature has emphasized dignity, respect, caring relationships, and professional accountability [9,17-19].

These contributions are necessary, but they do not fully resolve the point-of-care problem addressed here. Existing frameworks already address substantial elements of literacy, governance, communication, interpretation, and safety [1,6,11-16]. The remaining question is how these elements interact when AI becomes part of the way patients are represented, summarized, classified, and acted upon. A generated handoff note may be coherent while omitting uncertainty. A conversational AI system may provide accurate information while failing to recognize fear, shame, or confusion [7]. A staffing algorithm may optimize numbers while overlooking novice nurse support, skill mix, emotional labor, and team fatigue.

The critical question therefore shifts from "Can nurses use AI?" to "What must nursing preserve and govern when AI mediates how patients become known?" Tool use does not by itself constitute competence in AI-mediated care. Nursing competence also requires the ability to contextualize machine-generated information, recognize discordance between an output and the embodied patient, communicate uncertainty, and govern how AI changes professional behavior and clinical workflows.

Why MESH Now? From Decision Support to AI-Mediated Care

Urgency does not arise because AI has suddenly appeared in nursing. Rather, the nature and density of mediation are expanding. Earlier clinical decision support systems often delivered bounded alerts, rules, or predictions within specific tasks; contemporary generative and conversational AI systems can also summarize narratives, draft documentation, and produce patient-facing explanations, potentially functioning as an additional informational agent within clinician-patient interactions [7]. These developments increase the number of points at which machine-generated representations can shape attention, communication, and responsibility.

The need for MESH therefore rests not on technological novelty alone but on the increasing density of AI mediation across the clinical encounter. The same human factors problems observed with earlier automation—anchoring, overreliance, misuse, disuse, and automation bias—remain relevant [4,5]. What changes is the scale at which these effects may intersect with generated language, patient communication, documentation, and workflow governance.

Conceptual Positioning Among Existing Frameworks

In developing this viewpoint, we considered representative—not exhaustive—work in nursing AI literacy and competence, nursing AI governance, human factors, ethics, and implementation. This was a conceptual positioning exercise rather than a systematic literature search, and we do not claim to have excluded alternative frameworks through formal eligibility criteria.

Existing approaches already address substantial parts of the problem. The N.U.R.S.E.S. (navigate AI basics, utilize AI strategically, recognize AI pitfalls, skills support, ethics in action, and shape the future) guide emphasizes foundational AI literacy and responsible use [12]. NAIL-G (nursing artificial intelligence literacy and governance) integrates nursing AI literacy with sociotechnical safety and governance [11]. A modified Delphi study by Groeneveld et al [13] identified 10 competency domains for nurses working with AI-driven technologies, including interpretation of AI output, integration into clinical practice, communication, implementation, and evaluation. Human factors scholarship addresses automation bias, trust, use, misuse, and overreliance [4,5], while nursing ethics and relational scholarship emphasize dignity, respect, accountability, and the clinician-patient relationship [7-10,17,18].

MESH does not claim that these elements are absent from existing frameworks. Its proposed contribution is to bring them together around a nursing-specific question that becomes especially salient when AI mediates the point of care: how can nurses preserve contextual meaning-making and patient recognition while simultaneously governing behavioral drift, data visibility, workflow, and relational accountability? In this sense, MESH is an integrative lens for the interaction among domains that are often addressed separately, not a replacement for the frameworks from which those domains can be informed.

Standardized Nursing Data as a Bridge Between Humanistic Judgment and AI-Supported Decision-Making

Humanistic nursing judgment should not be positioned outside the data infrastructure of AI. Nurses continuously generate clinically meaningful information through assessments of symptoms, function, behavior, coping, care dependency, patient responses, and changes that may not yet be fully represented by conventional biomedical indicators. The challenge is that much of this knowledge may remain fragmented across narrative documentation or become insufficiently represented in the structured data used for digital decision support. As AI systems increasingly depend on structured clinical information, what becomes computationally visible may influence what becomes clinically salient.

Standardized nursing diagnoses, structured nursing assessments, Nursing Minimum Data Sets, and nursing-sensitive outcomes offer possible mechanisms for making nursing knowledge more visible within digital information infrastructures. In the protocol cited here, a Nursing Minimum Data Set is used to structure nursing diagnoses, nursing actions, and dimensions of care complexity [20]. Such standardization should not be interpreted as reducing nursing judgment to codes or as evidence that structured data automatically produce better or more humanistic AI. Rather, structured nursing data may provide one

XSL•FO
RenderX

informational bridge through which nursing-sensitive observations can become available for analysis while still requiring contextual interpretation.

Emerging evidence illustrates this potential. Cesare et al [21] used a machine learning approach to rank individual nursing diagnoses according to their predictive relevance for intensive care unit transfer. This finding should be interpreted cautiously: it does not establish that standardized nursing documentation automatically improves AI performance, nor does it imply that all dimensions of nursing judgment can be computationally encoded. It does show that structured nursing diagnoses may contain clinically meaningful information that is relevant to deterioration risk.

This distinction matters for humanistic nursing. Without adequate representation of nursing-sensitive information, AI systems may reproduce a predominantly biomedical view of the patient that underrepresents function, vulnerability, patient response, psychosocial concerns, care dependency, and other dimensions routinely recognized by nurses. Standardized nursing data are therefore treated in MESH as an enabling informational bridge—particularly for meaning-making and system and relational workflow governance—not as an additional framework domain. The relevant question is not whether nursing judgment should be human or data driven but how nursing knowledge can remain clinically meaningful, contextually interpreted, and professionally governed as portions of that knowledge become structured and computationally available.

When Machine-Generated Interpretation and the Patient Do Not Match

The following hypothetical emergency department vignette is clinically grounded and is intended to illustrate a class of machine-mediated interpretation errors rather than describe an identifiable patient.

An automated cardiac monitoring system displays a tachycardic rate. At the bedside, however, the nurse palpates a substantially slower pulse. Rather than accepting the displayed rate as definitive, the nurse reassesses the patient, reviews the waveform, obtains a more detailed medication history, and escalates the discordance for specialist review. Hospital-based continuous electrocardiogram monitoring systems can generate false-positive arrhythmia alarms, underscoring the need to interpret monitor output in conjunction with the patient and waveform rather than in isolation [22]. In this hypothetical scenario, the displayed tachycardic rate is recognized as a monitoring artifact rather than the patient's true pulse rate, while the actual bradycardia is clinically consistent with exposure to a glaucoma medication capable of systemic beta-blocking effects [23].

The clinical value of nursing judgment in this scenario lies not in rejecting technology but in recognizing that the machine-generated representation and the embodied patient do not correspond. Uncritical acceptance of the displayed rate could have prompted inappropriate tachyarrhythmia-directed evaluation or treatment. The monitor supplied a machine-generated representation; the nurse recognized the discrepancy and reconstructed its clinical meaning.

Conventional cardiac monitoring is not equivalent to contemporary generative AI. The vignette is used as an analogue of a broader machine-patient discordance problem rather than as evidence that all automated monitoring is AI. Across clinical technologies, machine-generated classifications can acquire cognitive prominence once integrated into clinical workflows. Human oversight is therefore necessary but not sufficient. Nursing requires accountable human presence: examining the patient, interpreting the clinical context, listening to the patient's story, communicating uncertainty, and taking responsibility when a technology-generated representation does not adequately reflect the person receiving care.

AI-Mediated Behavioral Drift

AI implementation can change more than information flow. As with earlier forms of automation, AI-enabled systems may alter attention, trust, questioning, communication, documentation, escalation, and responsibility [4,5]. These changes may occur gradually after implementation and may not be captured by conventional metrics such as adoption, usability, accuracy, or time saved.

We use the term "AI-mediated behavioral drift" provisionally to describe gradual, normalized postimplementation shifts across multiple professional behaviors—including attention, trust, communication, documentation, escalation, and accountability—rather than a single decision error or a synonym for automation bias. Automation bias concerns overreliance on automated output in judgment or decision-making [4]; misuse and disuse describe inappropriate patterns of automation use [5]. Behavioral drift, as proposed here, concerns how multiple AI-influenced behaviors may become normalized within clinical workflows over time. Examples may include looking first at a risk score rather than at the patient's embodied presentation, reproducing AI-generated summaries without sufficient contextual revision, or making disagreement with AI outputs difficult to document.

Such drift is not inevitable, but it warrants governance attention. In this viewpoint, behavioral governance does not mean disciplinary monitoring of individual nurses. It refers to governance of AI- and workflow-induced changes in professional attention, trust, communication, documentation, escalation, workflow, and accountability through AI system design, feedback loops, escalation structures, team learning, and nonpunitive review. Humanistic meaning-making requires calibrated trust: nurses need to judge when an output is clinically plausible, contextually incomplete, ethically concerning, or operationally useful [3-5]. Recognition of AI-clinical discordance—the mismatch between machine-generated output and bedside assessment—is therefore proposed as a candidate observable safety behavior rather than an informal act of professional intuition.

The MESH Framework

To move this discussion from abstract concern to practice-oriented inquiry, we offer MESH as a provisional conceptual framework for humanistic meaning-making and behavioral governance in AI-mediated nursing care. MESH denotes 4 domains—meaning-making, ethical presence, system and relational workflow governance, and human-in-the-relationship—and should not be confused with Medical Subject Headings (MeSH). In this domain, "system" refers to the sociotechnical health care environment and unit-level workflow in which AI is implemented, rather than only to an electronic health record system. MESH is offered in conversation with existing nursing AI literacy, competence, leadership, and governance frameworks [11-14]. It is not presented as a validated theory, complete competency model, or exhaustive taxonomy.

Meaning-making refers to the nursing capacity to interpret AI outputs through patient narratives, embodied assessment, family concerns, clinical trajectory, structured nursing data, and available resources. Ethical presence concerns the moral obligations that remain active during AI-mediated care, including dignity, autonomy, equity, advocacy, vulnerability, uncertainty, and moral accountability [8-10,17,18]. System and relational workflow governance concerns how AI system design, health care leadership, and unit-level workflow shape documentation, escalation, responsibility, invisible labor, and relational burden. Human-in-the-relationship concerns accountable human relational presence: the nurse remains responsible for listening, contextualizing, explaining uncertainty, responding to patient and family questions, supporting shared understanding, and ensuring that automated communication does not substitute for therapeutic interaction.

MESH is not intended to replace existing AI literacy, competency, ethics, leadership, or governance approaches [6,11-15,17-19], nor does it claim novelty for its component concepts. Its proposed contribution is their point-of-care integration around AI-mediated patient representation, nursing meaning-making, behavioral adaptation, nursing-data visibility, workflow governance, and relational accountability, together with translation of these concerns into provisional targets for education, implementation, audit, and empirical study.

What MESH Adds to Existing Frameworks

MESH does not aim to replace established nursing theories, AI competency frameworks, implementation science, human factors models, or approaches to AI literacy. Each contributes important concepts for understanding professional judgment, technology adoption, workflow, safety, ethics, and person-centered care [4,5,11-14]. The distinctive purpose of MESH is narrower: to organize these concerns around the conditions created when machine-generated information becomes an active intermediary in nursing care.

In AI-mediated practice, interpretation, relational recognition, behavioral adaptation, data representation, and workflow governance do not occur independently. An AI-generated recommendation may simultaneously redirect a nurse's attention, influence how a patient is interpreted, alter communication, modify escalation behavior, and redistribute accountability within workflow. Frameworks designed primarily to explain technology adoption, professional competency, ethical principles, or health care technology implementation may illuminate individual dimensions of this process without making their interaction at the point of nursing care explicit.

MESH therefore functions as an integrative nursing lens rather than a competing grand theory. Its contribution lies in connecting 4 concurrent questions: What does the AI output mean in this patient's context? What moral concerns and dimensions of the person remain visible? How is the technology shaping professional behavior, data visibility, and workflow? And who remains relationally present and accountable when nurses, patients, families, and AI-generated information interact? Its proposed contribution lies in this point-of-care integration and in translating these questions into observable targets for education, implementation, audit, and empirical research.

Operationalizing MESH in Clinical Practice

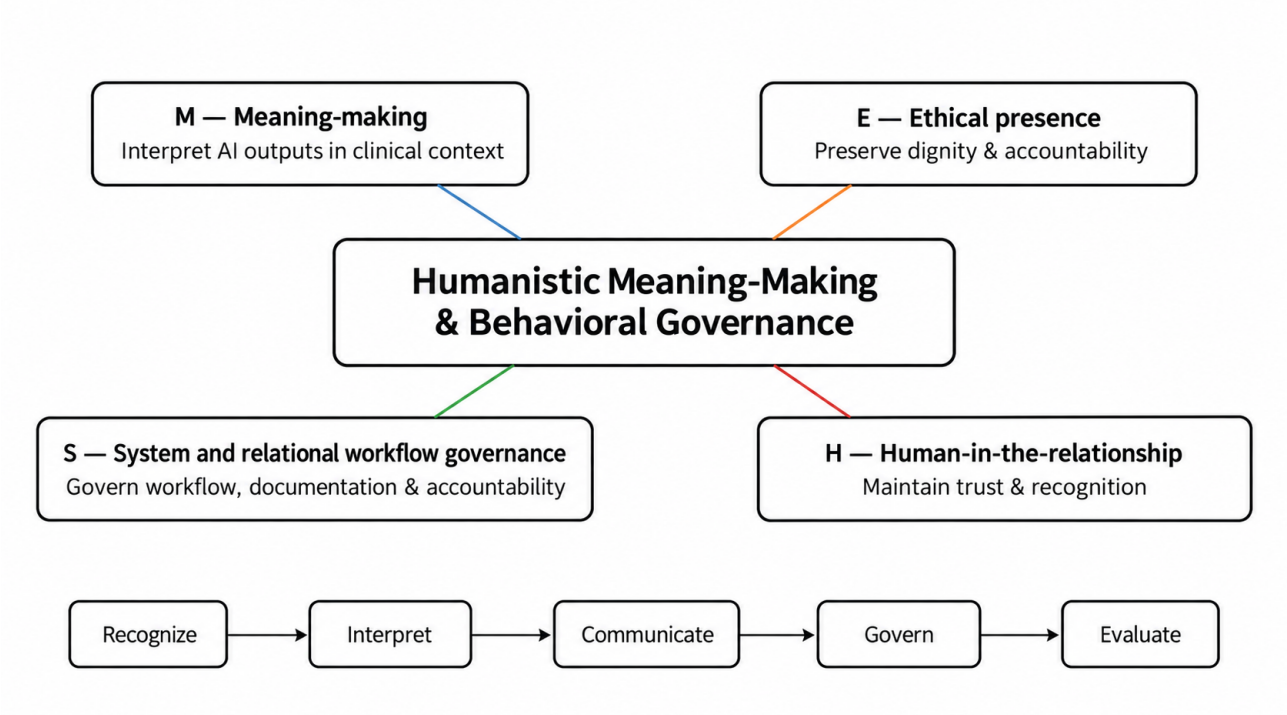
The practical value of MESH depends on whether its domains can be observed, taught, audited, and empirically examined. Table 1 therefore links each domain to a clinical question, observable indicators, implementation examples, and potential research directions. The indicators are intentionally provisional; they are not presented as validated measures. Rather, they illustrate how concepts such as patient recognition and behavioral drift can be converted into testable implementation constructs.

XSL•FO
RenderX

Table . Operationalizing the MESH (meaning-making, ethical presence, system and relational workflow governance, and human-in-the-relationship) framework in AI-mediated nursing care.

MESH domain	Key clinical question	Observable indicators	Example implementation	Future empirical direction
Meaning-making	Does the AI output improve or distort the interpretation of this patient's situation?	Nurse compares output with bedside assessment, patient narrative, trajectory, family context, and structured nursing information; AI-clinical discordance is recognized and investigated as a candidate safety behavior.	A cardiac monitor displays a tachycardic rate that conflicts with the palpated pulse; the nurse reassesses, reviews the waveform and medication history, and escalates the discrepancy rather than treating the machine-generated display as definitive.	Candidate indicators: frequency and resolution of AI-clinical discordance, override patterns, missed contextual cues, and escalation consequences.
Ethical presence	Does AI-mediated care preserve moral obligations related to dignity, autonomy, equity, advocacy, vulnerability, and uncertainty?	Patient preferences, vulnerability, goals, concerns, and ethically relevant uncertainty remain visible in documentation and decision-making.	AI-generated discharge information is reviewed and adapted to the patient's comprehension, concerns, family or community support, and ability to self-manage.	Candidate indicators: omission of preference-sensitive information, perceived respect, trust, and individualized care measures.
System and relational workflow governance	How does AI alter attention, escalation, accountability, workload, documentation, and relational work?	Defined escalation and override pathways, audit trail, alert and documentation burden monitoring, frontline feedback, and nonpunitive review of recurrent AI-influenced workflow problems.	A unit reviews recurrent overrides, alert fatigue, delayed responses, documentation revisions, and examples of behavioral drift at regular governance meetings.	Candidate indicators: alert fatigue, automation bias, behavioral drift, escalation performance, workload, and documentation burden.
Human-in-the-relationship	Does AI augment rather than substitute accountable human relational presence?	Nurse listens, contextualizes, explains uncertainty, responds to questions, supports shared understanding, and remains accountable for communication.	AI prepares preliminary education or summarizes information; the nurse verifies it, explains uncertainty, and contextualizes it through conversation and teach-back.	Candidate indicators: patient comprehension, shared understanding, teach-back performance, trust, and perceived relational quality.

The MESH-Action Cycle



A conceptual lens that identifies a problem but does not support application is of limited value for nursing leadership. We therefore pair the 4 MESH domains with a 5-step MESH-action cycle: recognize, interpret, communicate, govern, and evaluate. MESH identifies what should be examined and preserved; the action cycle is a practice-oriented application pathway for beginning that work, not a second framework or theory. Each step draws on established bodies of knowledge. Figure 1 illustrates the relationship between the four MESH domains and the MESH-action cycle. Table 2 summarizes the five steps of the MESH-action cycle, including the corresponding leadership actions, intended purposes, and supporting knowledge bases.

XSL•FO
RenderX

Table . MESH (meaning-making, ethical presence, system and relational workflow governance, and human-in-the-relationship)-action cycle for nurse leaders.

Action	Nurse leaders should...	Purpose	Starting knowledge base
Recognize	Identify how AI reshapes attention, trust, communication, documentation, data visibility, and accountability	Detect behavioral drift and representational gaps early	Human factors, usability, and safety science [4,5]
Interpret	Train nurses to compare AI outputs with bedside assessment, patient narratives, family concerns, structured nursing data, and clinical trajectory	Prevent automation bias, premature closure, and unexamined discordance	Clinical reasoning, automation bias, calibrated trust, and AI competency work [3-5,13]
Communicate	Prepare nurses to explain AI-supported care and uncertainty in language that preserves trust and understanding	Maintain patient and family recognition and participation	Therapeutic and relational communication, respect, and shared understanding [7-10,13]
Govern	Establish escalation, override, documentation, and feedback pathways when AI and nursing judgment diverge	Protect accountability, safety, and professional agency	Sociotechnical safety, implementation science, and nursing leadership and governance [1,11,14,15]
Evaluate	Use nursing-sensitive, behavioral, relational, and humanistic indicators in addition to accuracy, adoption, and efficiency metrics	Ensure AI-supported care remains clinically meaningful and humane	Nursing-sensitive outcomes and implementation evaluation [1,13,15,16]; human factors and automation research [4,5]

Figure 1. The MESH (meaning-making, ethical presence, system and relational workflow governance, and human-in-the-relationship) framework and MESH-action cycle for AI-mediated nursing care. The 4 MESH domains identify what nursing should examine and preserve in AI-mediated care, whereas the 5-step MESH-action cycle provides a practice-oriented pathway for applying these domains in leadership, education, implementation, and evaluation; it is not a second framework or theory.

"Recognize" can draw on human factors and safety science to identify AI-induced changes in attention, trust, communication, data visibility, workflow, and accountability before they become normalized [4,5]. "Interpret" builds on clinical reasoning, automation bias research, calibrated trust, and AI competency work to reconcile machine output with the embodied patient, narrative, nursing data, trajectory, and context [3-5,13]. "Communicate" focuses on AI-supported information, uncertainty, therapeutic communication, and shared understanding [7-10,13]. "Govern" draws on sociotechnical safety, implementation, and nursing leadership scholarship to establish escalation, override, accountability, audit trails, and feedback systems [1,11,14,15]. "Evaluate" extends technical performance assessment to candidate nursing-sensitive,

XSL•FO
RenderX

behavioral, relational, workload, and patient-experience consequences [1,4,5,13,15,16].

Potential indicators include AI-nursing judgment discordance, documented rationales for overriding AI recommendations, alert burden, AI-generated documentation revision rates, patient understanding of AI-supported care, family communication concerns, staff confidence, missed care, perceived moral distress, and nursing-sensitive outcomes. These indicators do not replace technical evaluation; they broaden evaluation to the human and professional consequences of implementation.

AI as an Enabler and Risk Amplifier of Humanistic Care

AI should not be framed only as a threat to humanistic nursing. Reviews of AI-based technologies in nursing describe applications in decision support, prediction, education, and workflow-related functions [1,6,16]. Generative and conversational systems may additionally support information synthesis and communication [7]. Whether these functions actually reduce cognitive or administrative burden or create more time for relational care is an empirical question rather than an assumed benefit. Under appropriate conditions, however, AI may support rather than diminish humanistic care.

At the same time, the humanistic consequences of AI are not inherent properties of the technology; they are produced through its design, data, interpretation, implementation, and governance. The same AI-enabled clinical information system that surfaces a clinically meaningful pattern can also promote automation bias; the same generated summary that reduces documentation effort can narrow a clinical narrative; and the same decision support tool that standardizes care can shift responsibility or normalize behavioral drift [3-5,7].

The relevant distinction is therefore not humanistic nursing vs AI but humanistically governed AI vs poorly governed AI-mediated care. AI outputs should function as inputs into nursing meaning-making, not as substitutes for it. The objective of governance is to preserve the benefits of computational support while maintaining contextual judgment, patient recognition, and professional accountability.

Professional Advocacy and Leadership Implications

Nursing should not be positioned merely as the workforce that adapts to AI-enabled technologies after they are designed, purchased, and implemented [1,14,15,17,18]. Nurses and nurse leaders are governance actors because AI-enabled clinical information systems can alter clinical attention, documentation, escalation, workload, patient communication, and the visibility of nursing knowledge.

At the unit level, MESH may guide organizations to examine more than technical infrastructure and staff training. Candidate governance questions include where AI-generated information enters clinical workflows, what nursing-sensitive information is included or omitted, who remains accountable when AI and bedside assessment diverge, whether escalation and override pathways are available, how alert and documentation burden change, and whether frontline feedback identifies recurrent mismatches between AI-enabled clinical information system outputs and clinical reality. These questions are intended for organizational learning rather than individual surveillance or blame.

For nursing education, MESH may extend AI literacy toward AI-mediated clinical reasoning [4-6,12]. Simulation could expose learners to plausible but incomplete outputs, conflicting bedside findings, and situations in which AI-generated communication requires contextual revision. Training can cultivate calibrated trust rather than blind compliance or defensive rejection.

For research, validation should proceed in stages rather than assume that MESH improves outcomes. Initial qualitative work and stakeholder consultation could refine domain boundaries and language. Delphi studies could then assess content relevance and clarity among frontline nurses, nurse leaders, informaticians, patients, and ethicists. Subsequent work could develop candidate indicators or audit items and test them in simulation or observational studies, including recognition of AI-clinical discordance and override behavior. Only after conceptual and operational refinement should implementation studies examine feasibility, acceptability, workflow effects, patient experience, and associations with nursing-sensitive outcomes.

Limitations and Future Validation

The MESH framework is proposed as a provisional conceptual framework rather than an empirically validated model. Its purpose is to organize emerging concerns in AI-mediated nursing care and generate practice-oriented questions for education, leadership, implementation, and research. We do not claim that the 4 domains are exhaustive, universally applicable, psychometrically established, or unique in their component concepts.

The framework's proposed contribution is integrative rather than exclusive. The conceptual positioning in this viewpoint was based on a nonsystematic comparison of representative frameworks and was not intended to establish that MESH uniquely incorporates concepts absent from all previous models. Future work should test whether its domains are distinct, useful, measurable, and applicable across clinical contexts. The proposed operational indicators require further empirical development and validation, while the relationship between standardized nursing data and AI-supported decision-making warrants investigation beyond its early applications in predictive modeling. MESH should therefore be understood as a starting language for inquiry and governance, not as a final competency standard.

Conclusions

AI will increasingly shape nursing practice, but the central issue is not whether nursing becomes more or less technological. It is whether nursing judgment, nursing-sensitive information, patient recognition, and professional accountability remain visible and actionable within technology-mediated care. Existing

XSL•FO
RenderX

AI literacy and governance frameworks provide an essential foundation [6,11,12,14,17-19]; an important next task is to examine what happens when AI enters not only the workflow but also the process through which patients become known [7-10].

To move from general readiness to practice-level evaluation, nursing needs a structured way to examine how AI-mediated care affects interpretation, patient recognition, workflow, and relationships at the point of care. This viewpoint offers MESH as a provisional integrative nursing lens and the MESH-action cycle as a practice-oriented application pathway for leadership, education, implementation, and research. The central claim is not that nursing should resist AI or that MESH introduces unprecedented component concepts. Its proposed value lies in integrating nursing meaning-making, ethical presence, nursing-data visibility, AI-induced behavioral and workflow change, and accountable human presence at the point where AI mediates how the patient is represented and understood.

When AI helps the health care system detect patterns in patient data, nursing must ensure that the patient remains recognized as a person whose experiences, vulnerabilities, preferences, and context matter.

Generative AI Use

During manuscript preparation and revision, the author used ChatGPT (GPT-5.6 Sol; OpenAI, 2026) to assist with language editing, organization and refinement of arguments, drafting and refinement of responses to peer-review comments, consistency checking, and preparation of the schematic layout for Figure 1 based on the author-developed MESH concepts. The author critically reviewed and revised all AI-assisted output, independently verified factual claims and cited sources, and takes full responsibility for the final content of the manuscript. Generative AI was not used as an author or as an independent source of evidence.

Funding

This work received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Data Availability

Data sharing is not applicable to this viewpoint because no datasets were generated or analyzed.

Authors' Contributions

TH conceptualized the manuscript, developed the MESH framework and MESH-action cycle, drafted and revised the manuscript, and approved the final version for submission.

Virtual Reality–Enabled Physical AI Training for Supportive Nursing Robotics: Nurse-in-the-Loop, Site-Specific Conceptual Framework

Seungman Kim, PhD, MEd

School of Nursing, Texas Tech University Health Sciences Center, 3601 4th Street, Lubbock, TX, United States

Abstract

Interest in physical AI and robotics in health care is increasing, but the nursing literature shows that the evidence base remains early, nurse-centered applications are underdeveloped, and real-world experiential evidence is limited. Nurses are more likely to accept robots that reduce physically demanding and repetitive work while preserving the interpersonal and judgment-intensive core of nursing practice. This conceptual paper proposes a nursing-centered framework in which virtual reality functions not merely as a simulator but as a scaffolded training infrastructure for supportive physical AI systems, enabling nurse augmentation, site-specific adaptation through digital twins, and staged simulation-to-real transfer. The framework was developed through a conceptually integrative and implementation-aware synthesis drawing on nursing robotics, AI in nursing, immersive simulation, digital twins, human-in-the-loop learning, and physical AI development literature. It is organized around 5 linked elements and supported by a 4-layer technical architecture that outlines functional requirements and implementation pathways. Four key propositions ground the framework: (1) nursing robot training should focus on competency formation, not on decontextualized data accumulation; (2) training should proceed through progressive fidelity and staged autonomy; (3) digital twins should function as operational bridges for local ward adaptation; and (4) simulation-to-real transfer should be governed by explicit nursing-relevant validation criteria and retained human accountability. The proposed nurse-in-the-loop, site-specific virtual reality framework offers a nursing-centered complement to general-purpose physical AI pipelines by making workflow fit, role boundaries, local adaptation, and governed transfer explicit design requirements.

Introduction

AI in nursing has advanced rapidly in decision support, workflow optimization, and documentation, yet embodied AI for nursing remains underdeveloped as a clinically grounded field. Recent umbrella and scoping reviews show unresolved ethical, social, and implementation questions, while robotics reviews suggest that the evidence base is early and that explicitly nurse-centered robotic support remains limited [1,2]. Shaw and Chen [3] identify physical AI as a nascent but consequential frontier for nursing, emphasizing that robotics applications must be evaluated through nursing-specific lenses rather than imported wholesale from industrial or general-purpose contexts. Qualitative synthesis further confirms that nurses perceive AI adoption as acceptable only when it preserves professional autonomy and relational care [4].

Nursing work is not simply a set of motor actions. It is dynamic, interruption-prone, socially dense, ethically constrained, and deeply local. A single nurse on a medical-surgical unit may manage 6 or more patients simultaneously, responding to unpredictable deteriorations, coordinating with multiple disciplines, and making real-time prioritization decisions that cannot be reduced to algorithmic rules. Whether a robot can function appropriately in this context depends not only on navigation or manipulation capabilities but also on understanding role boundaries, fitting into existing workflows without creating new burdens, supporting appropriate escalation when uncertainty arises, and preserving the human clinical judgment that remains the irreducible core of safe patient care [5,6]. These requirements are not peripheral constraints to be addressed after technical development; they are the design specifications that should drive development from the outset.

Industry-scale physical AI platforms such as Cosmos (NVIDIA) and Isaac Sim (NVIDIA) provide powerful enabling technologies—world foundation models, synthetic data generation, physically based simulation—that future nursing robotics will leverage. These platforms have demonstrated remarkable progress in warehouse logistics, manufacturing, and autonomous driving, where environments are relatively structured and task specifications can be defined independently of individual human relationships. However, these platforms

XSL•FO
RenderX

are optimized for generalizable autonomy at scale, whereas nursing requires an additional nurse-centered orchestration layer that addresses workflow fit, role clarity, safety governance, and local adaptation as first-class design requirements. The gap is not primarily technological; it is translational. The enabling components exist, but the orchestration layer that connects them to nursing's specific clinical, ethical, and organizational realities does not.

This paper proposes a nurse-in-the-loop virtual reality (VR) framework with site-specific digital twin alignment and governed simulation-to-real transfer. The framework contributes both a conceptual structure and a practical technical architecture, the latter detailed in Multimedia Appendix 1 to support the assessment of conceptual plausibility and future empirical implementation.

The framework was developed through a conceptually integrative synthesis rather than a systematic review, and the procedure is made explicit here for transparency. Source literature was identified purposively across 6 domains—nursing robotics, AI in nursing, immersive simulation, digital twins, human-in-the-loop learning, and physical AI development—prioritizing peer-reviewed work, recent reviews and authoritative reports (including systematic reviews, umbrella reviews, and a National Academies report), and sources judged relevant to the translational question of how nursing expertise can govern robot learning. This selection was purposive and interpretive rather than exhaustive or reproducible in the sense of a systematic search protocol. Synthesis proceeded thematically. Recurring requirements and constraints were extracted across these domains and grouped into the dimensions that structure the framework: task decomposition, expert-in-the-loop learning, fidelity progression, local adaptation, and governed transfer. Conceptual abstraction then moved from specific technologies and empirical findings to architecture-level principles, distilling the recurring patterns into the 4 propositions that ground the framework and into the 5 linked elements and 4-layer architecture that operationalize them. The framework is therefore a structured, literature-grounded hypothesis whose components are intended to be tested empirically rather than a set of validated findings.

Why Nursing Requires a Distinct Physical AI Training Paradigm

Reviews consistently show nurses prefer robots that reduce physically burdensome repetitive work while preserving interpersonal and judgment-intensive care [7]. A systematic review of collaborative robots found that most applications are patient-centered rather than nurse-centered, and an umbrella review identified persistent concerns around patient safety, liability, and ethics [1,2]. This pattern reveals a fundamental misalignment in how nursing robotics has been conceived: robots are designed for tasks defined by engineers or physicians, then offered to nurses as end users, rather than developed from the outset around nurse-identified needs and nurse-defined boundaries. The consequence is a literature rich in technical demonstrations but thin on evidence of sustained clinical adoption, workflow integration, or measurable workload relief for nursing staff.

The relevant design question is therefore not "How can we maximize robotic autonomy?" but "Which parts of nursing work are appropriate for bounded robotic support, under which workflow and safety constraints, and with what forms of nurse oversight?" This reframing has several implications. It shifts the unit of analysis from the robot's capabilities to the nurse's workflow. It requires that task selection be informed by practicing nurses rather than inferred from external observation. It demands that autonomy levels be calibrated to clinical risk rather than maximized for technical elegance, and it positions evaluation around nursing-relevant outcomes, including workload relief, trust, care quality, and escalation appropriateness, rather than task success rates in isolation. Collectively, these shifts define a translational agenda that positions nurses as architects of robotic scope rather than recipients of autonomous systems.

A Nurse-in-the-Loop, Site-Specific Conceptual Framework

Framework Structure and Training Progression

The framework organizes VR-based physical AI training into 5 linked elements, summarized in Table 1. Figure 1 summarizes the proposed architecture and its feedback loops. In this framework, progressive fidelity refers to the structured increase of environmental and behavioral complexity across training tiers; staged autonomy refers to calibrating the robot's permitted actions to clinical risk; and governed transfer refers to treating simulation-to-real progression as a gated clinical-governance decision rather than a purely technical step. The 5 elements proceed sequentially but include feedback loops: nurse-in-the-loop corrections at each fidelity stage feedback to refine the task library and role-boundary map, while digital twin synchronization provides continuous environmental grounding across all training stages. The governed transfer element enforces stage-gate progression, ensuring that advancement from simulation to physical deployment is conditioned on explicit nursing-relevant validation criteria rather than technical metrics alone.

XSL•FO
RenderX

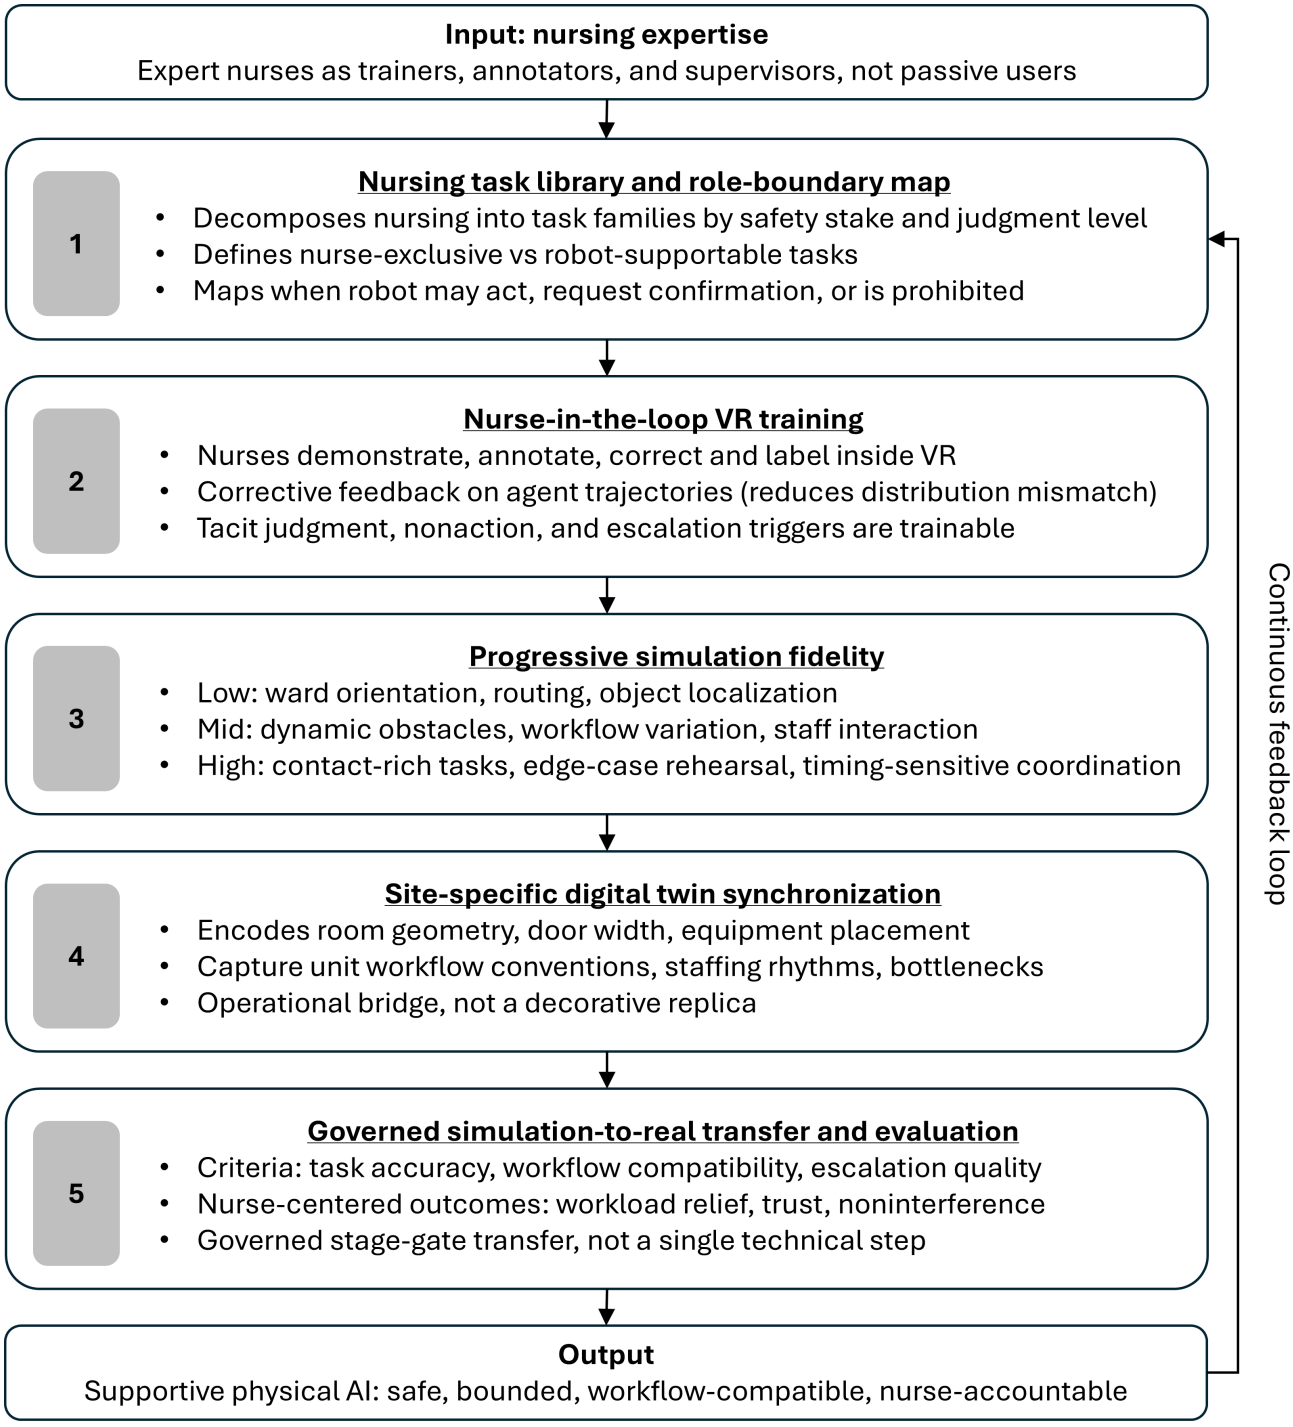

Table . The 5 linked elements of the nurse-in-the-loop, site-specific framework, with the purpose and core mechanism of each.

Element	Purpose	Core mechanism and output
Nursing task library and role-boundary map	Define which nursing tasks are appropriate for bounded robotic support and at what level of autonomy	Decomposes nursing into task families by safety stakes, paired with a 4-zone boundary map: independent execution, nurse-confirmed execution, gated expansion, and permanently prohibited action
Nurse-in-the-loop VR[a] training	Capture expert nursing judgment as the primary training signal rather than treating nurses as end users	Inside VR, nurses demonstrate tasks, annotate context, correct trajectories, label unsafe actions with explanations, and set escalation thresholds, yielding multimodal input richer than conventional labeled datasets
Progressive simulation fidelity	Build robot competence incrementally and avoid premature exposure to clinical complexity	Structured low-fidelity, midfidelity, and high-fidelity tiers, with promotion to a higher tier contingent on demonstrated performance at the current tier
Site-specific digital twin synchronization	Adapt generic robot capabilities to the physical and operational realities of one clinical unit	A continuously synchronized operational model constrained to variables that materially affect task performance: room geometry, equipment, circulation pathways, staffing density, and workflow conventions
Governed simulation-to-real transfer and evaluation	Condition physical deployment on nursing-relevant validation rather than on technical metrics alone	Staged validation gates, each with explicit sign-off and mandatory regression on degradation, evaluated against workload relief, nurse trust, and care quality

Figure 1. Nurse-in-the-loop, site-specific conceptual framework for virtual reality (VR)–based physical AI training in nursing.

Nursing Task Library and Role-Boundary Map

Rather than treating "nursing" as a single training domain, the framework decomposes nursing into task families with different safety stakes, data needs, and permissible autonomy levels. This decomposition is essential because the spectrum of nursing work ranges from logistical tasks with minimal patient contact (eg, supply transport between a storage room and a nurses' station) to high-acuity interventions requiring moment-to-moment clinical judgment (eg, responding to hemodynamic instability). Treating these as a single training domain would either constrain the robot to trivial functions or expose patients to premature autonomy in high-stakes situations.

Near-term supportable tasks include supply transport, room-to-room delivery, retrieval of noncontrolled materials, and bounded monitoring-support workflows such as periodic vital sign equipment checks. The framework's clinical scope is delimited accordingly: it is confined to supportive tasks—noncontact logistical and environmental tasks in its initial scope, with possible extension to direct physical assistance such as patient repositioning support only under the staged validation gates—and it permanently excludes surgical or otherwise invasive intervention, medication administration, and independent clinical judgment, including autonomous decisions based on the interpretation of physiological signals, all of which remain with the nurse and clinical team. The task library is

XSL•FO
RenderX

paired with a role-boundary map that defines 4 zones of permissible action: independent execution (low-risk, logistical tasks with no patient contact), nurse-confirmed execution (tasks requiring verification before action, such as delivering items to a specific patient room), gated expansion (tasks involving direct physical assistance, such as patient repositioning support, which fall outside the autonomy permitted at the framework's initial stage and may be introduced only progressively under the staged validation gates described in layer 4), and permanently prohibited action (medication administration and independent clinical decision-making, which remain reserved to the nurse at all stages). This graduated boundary structure ensures that autonomy is not a binary on or off switch but a spectrum aligned with clinical risk, in which direct-contact assistance is neither categorically excluded nor permitted at the outset but is gated behind staged, nurse-governed validation.

Nurse-in-the-Loop VR Training

Nurses are expert contributors to policy formation, not passive end users. This distinction is not merely rhetorical; it determines the entire data collection and learning paradigm. In VR, nurses serve multiple roles simultaneously: they demonstrate tasks by performing them in the simulated environment; annotate contextual factors that affect task execution (eg, "this corridor is typically congested at shift change"); correct robot trajectories when the agent's behavior deviates from acceptable practice, label actions as unsafe or inappropriate with explanations; and define the escalation thresholds that determine when the robot should pause and request human guidance. This multimodal expert input is substantially richer than the labeled datasets typically used in supervised robot learning, because it captures not only what to do but also why, when, and under what conditions actions are appropriate or inappropriate. The approach is consistent with interactive imitation learning, which demonstrates that corrective feedback on agent trajectories in the agent's own state distribution reduces compounding errors more effectively than offline demonstration alone [8]. It also aligns with human-in-the-loop optimization research showing that iterative human participation in the learning loop produces applied robotic systems that better match real-world task requirements [9].

Progressive Simulation Fidelity

Fidelity is matched to learning objectives rather than maximized indiscriminately. A common assumption in simulation-based training is that higher fidelity is always better; however, this is not supported by the evidence. Excessively complex environments can impede early-stage learning by introducing irrelevant variation before foundational competencies are established. This staged approach draws on the scaffolding principle in learning theory, in which task complexity is incrementally increased as competence develops [10]. Applied here, the robot's training environment progresses through structured tiers of environmental and behavioral complexity, with promotion to a higher-fidelity tier contingent on demonstrated performance at the current tier. This prevents the robot from encountering clinical complexity it is not yet equipped to handle. Meta-analyses confirm that structured VR environments improve knowledge acquisition, skill development, and problem-solving in nursing education [11-14], and the same principle applies to robot training: structured progression through complexity produces more robust and generalizable policies than exposure to full complexity from the outset. The 3 fidelity tiers are defined as follows: low fidelity: ward orientation, routing, object localization, and collision avoidance; mid fidelity: dynamic obstacles, workflow variations, staff interactions, and monitoring support; high fidelity: contact-rich assistance, edge-case rehearsal, and timing-sensitive coordination.

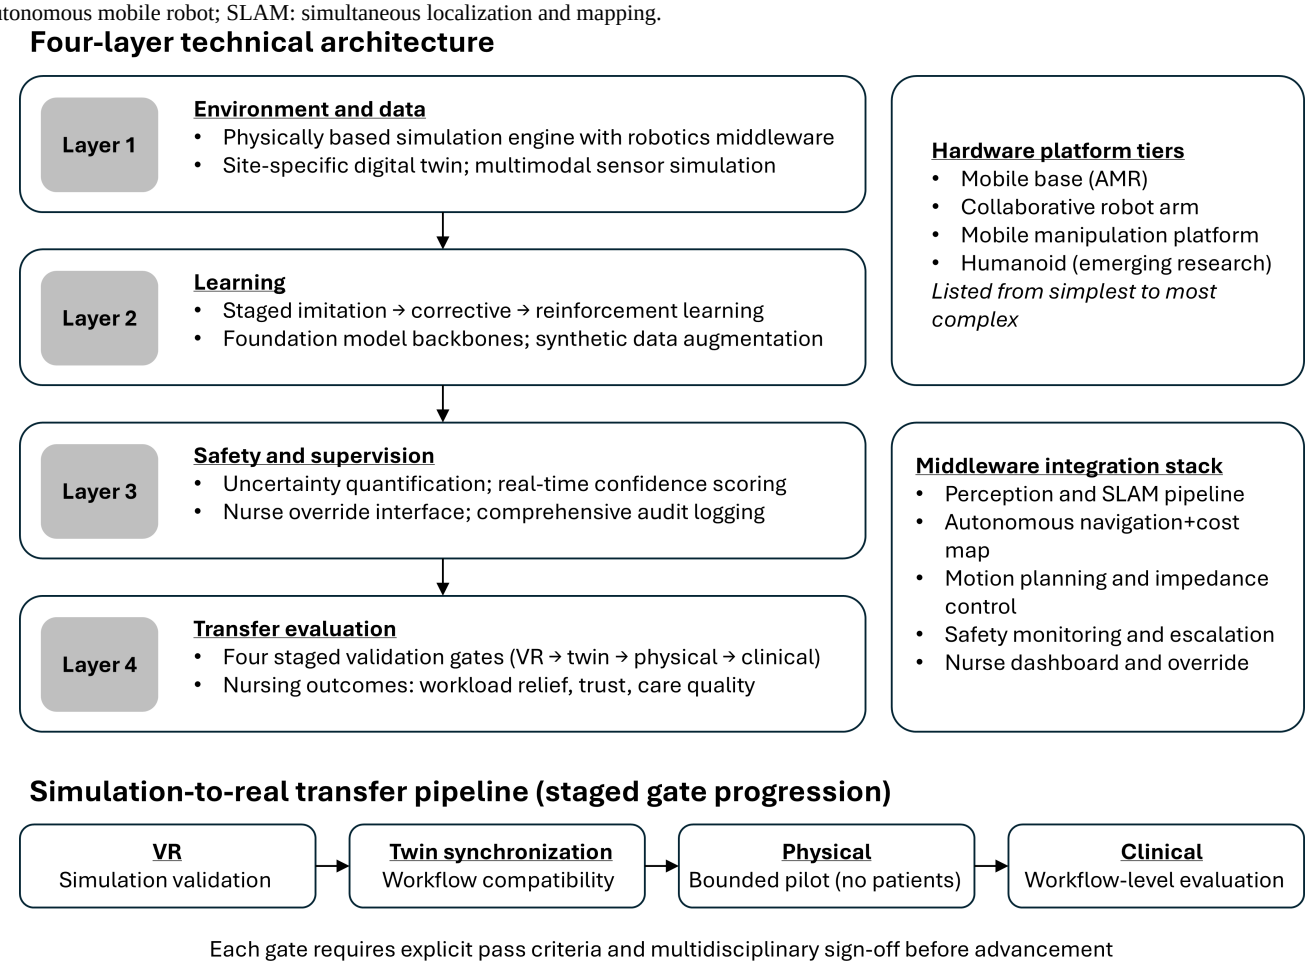
Site-Specific Digital Twin Synchronization

In this framework, the digital twin is defined as a continuously synchronized operational model of a specific nursing unit, constrained to the variables that materially affect robotic task performance, rather than a comprehensive, photorealistic, or static replica. It is an operational bridge, not a decorative replica. The distinction matters because health care digital twin implementations vary enormously in scope and ambition, from comprehensive hospital-wide models to narrowly scoped process simulations. A recent National Academies report identifies foundational research gaps in digital twin validation, interoperability, and domain-specific adaptation, cautioning that the term is frequently applied to systems that lack the bidirectional synchronization and predictive capability that define a true twin [15]. Health care–specific reviews note similar definitional variability and largely partial implementations [16-18]. The pragmatic approach adopted here constrains the twin to the minimum set of variables that materially affect robotic task performance in a specific nursing unit: room geometry and doorway clearances, equipment locations and dimensions, circulation pathways and bottlenecks, staffing density patterns, and unit-specific workflow conventions such as supply routes and shift-change traffic patterns. This constraint is deliberate. An overly ambitious twin risks becoming an engineering project in itself, diverting resources from the core research questions. A pragmatically scoped twin, by contrast, serves its intended function—bridging the gap between a generic simulation and the particular physical and operational realities of the deployment site—without requiring comprehensive hospital informatization as a prerequisite.

The level of fidelity a twin requires is determined by what the task depends on. Supportive tasks, such as navigation, transport, retrieval, and environmental monitoring, depend on spatial geometry, circulation patterns, equipment placement, and workflow timing, all of which the pragmatic twin represents; they do not depend on patient-specific anatomy or tissue behavior. Surgical tasks, by contrast, depend on patient-specific anatomical structure, tissue deformation, and submillimeter spatial accuracy, which is why surgical applications require high-fidelity, patient-specific twins. The pragmatic twin is therefore not an oversimplified version of a surgical twin but a different object matched to a different task class: for supportive nursing tasks it is sufficient, whereas for surgery it would be inadequate. Framing twin fidelity as task-determined, rather than as a single scale of ambition, clarifies why the scoping adopted here is appropriate rather than simplistic.

XSL•FO
RenderX

Governed Simulation-to-Real Transfer and Evaluation



Transfer criteria extend beyond task success to include workflow compatibility, interruption recovery, escalation quality, and noninterference with bedside care. In conventional robotics, simulation-to-real transfer is treated primarily as a technical challenge: closing the gap between simulated and physical dynamics through domain randomization [19], dynamics randomization [20], and system identification. These techniques remain essential and are incorporated into the framework's technical architecture (Multimedia Appendix 1). However, in a nursing context, the transfer gap is not only physical but also social, organizational, and ethical. A robot that navigates a physical ward successfully may still fail if it disrupts nurse workflow, creates alarm fatigue through excessive escalation, or undermines patient trust through inappropriate proximity or timing. Therefore, simulation-to-real transfer is treated here as a governance event rather than a final technical step. Transfer proceeds through staged validation gates, each requiring explicit sign-off before progression. This stage-gate structure ensures that technical performance is necessary but not sufficient for clinical deployment; nursing-relevant outcomes, including measurable workload relief, nurse trust as assessed by validated human-robot interaction scales, and care quality indicators, are the ultimate evaluation standard.

Conceptual Technical Architecture

Four-Layer Technical Architecture

The framework is grounded in a 4-layer technical architecture (Figure 2), with illustrative implementation options. The conceptual reference architecture, including evaluation logic and architectural requirements for each layer, is provided in Multimedia Appendix 1. Throughout this section, the contribution lies in the layered functional structure of each layer rather than in any specific product or method; all named technologies are current illustrative instantiations that satisfy a layer's functional requirements and may be substituted by implementing teams as the tooling landscape evolves.

Figure 2. Four-layer technical architecture and simulation-to-real transfer pipeline for virtual reality (VR)–based physical AI training in nursing. AMR: autonomous mobile robot; SLAM: simultaneous localization and mapping.

Layer 1: Environment and Data

The VR environment requires graphics processing unit–accelerated, physically based simulation with direct interoperability with robotics middleware, specifically Robot Operating System 2 (ROS 2); platforms such as Isaac Sim or Unity with a ROS 2 bridge are illustrative options that meet this requirement. For example, Isaac Sim provides native integration with a physics engine supporting both rigid and deformable body dynamics—useful for simulating clinical equipment interactions—together with built-in synthetic data generation. These are cited as representative current tools rather than as required choices; the functional requirement, not the specific platform, is what the framework specifies. Site-specific digital twins are constructed via light detection and ranging scanning

XSL•FO
RenderX

or photogrammetry of target clinical units, with the resulting 3D environments synchronized with operational workflow data drawn from structured observation and, where available, real-time locating system feeds. Multimodal sensor channels are simulated within the environment to match the sensor configuration of the target physical robot platform. For the noncontact logistical and environmental tasks that constitute the framework's initial scope, the active sensing channels are red, green, blue, and depth cameras, light detection and ranging, and inertial measurement units. Force and haptic channels are additionally represented in simulation to preserve fidelity with contact-capable platforms, including collaborative-arm and emerging humanoid configurations, which increasingly incorporate fingertip tactile and joint-level force-torque sensing as standard equipment. Because simulation-to-real transfer requires the simulated sensor suite to mirror the deployed platform, these contact channels are not engaged as policy inputs for noncontact tasks; they become active only if and when the framework is extended to contact-rich assistance under the staged validation gates (layer 4). Expert demonstrations and corrective feedback are captured as structured task-state logs, including joint positions, end-effector poses, gaze direction, verbal annotations, and contextual state labels.

Layer 2: Learning

The learning layer operates in 3 sequential phases, each defined by its functional role rather than by a specific algorithm. First, foundation policy formation (eg, behavioral cloning from expert nurse demonstrations) provides a policy that captures the basic structure of each task. Second, interactive correction, using methods such as dataset aggregation (DAgger) or intervention-weighted regression, refines this policy by incorporating nurse feedback on the robot's own attempted trajectories, weighting corrections by intervention timing and confidence to address the distribution mismatch problem inherent in offline imitation learning [21]. Third, policy optimization (eg, reinforcement-learning fine-tuning with algorithms such as proximal policy optimization or soft actor-critic under nursing-specific reward shaping) optimizes the policy for task completion, safety margins, workflow timing, escalation quality, and trajectory smoothness. Pretrained robot foundation-model backbones, such as OpenVLA [22] or Octo [23], may be leveraged to reduce data requirements and improve generalization across task families. The named methods are representative instances of each functional role and may be substituted as the field advances. Synthetic data augmentation using domain randomization and world foundation models expands coverage of rare but safety-critical clinical edge cases, such as unexpected patient falls, equipment malfunctions, or crowded corridor scenarios, without requiring real-world exposure to these events. Importantly, reinforcement-learning fine-tuning is not proposed as a means of solving contact-rich reality-gap problems in simulation; rather, it is applied incrementally only after lower-risk policies have passed the staged validation gates and only within the constraints of supervised real-world evaluation.

Layer 3: Safety and Supervision

The safety layer crosscuts all other layers and operates at multiple timescales. At the real-time level, uncertainty quantification via Monte Carlo dropout or conformal prediction generates continuous confidence scores for the robot's actions and perceptions. Hard stop rules trigger immediately when force thresholds are exceeded, when confidence drops below task-specific thresholds (τ), or when the robot detects an unrecognized situation outside its training distribution. A nurse override API, implemented as a ROS 2 action server, allows real-time human intervention with a target response latency of less than 500 milliseconds. At the session level, all decisions, confidence scores, escalation events, and nurse override instances are logged in a structured format for post hoc audit. These logs serve dual purposes: they provide the audit trail necessary for institutional safety review, and they generate the training signal for policy refinement in subsequent learning iterations. The safety layer embodies the principle that the robot should fail conservatively: when uncertain, it should stop and escalate rather than proceed with a potentially harmful action.

Layer 4: Transfer Evaluation

Transfer proceeds through 4 stage gates, each with explicit pass or fail criteria and required sign-off before advancement. Gate 1 validates VR against task accuracy, collision rate, and escalation quality benchmarks. Gate 2 validates in the digital-twin–synchronized environment for workflow compatibility, route efficiency, and timing alignment with shift-level task patterns. Gate 3 involves bounded physical pilot deployment in a controlled clinical area without patients, evaluating physical task performance, nurse override latency, and usability. Gate 4 extends to workflow-level evaluation in a real clinical unit under supervision, integrating nursing-relevant outcomes, including measurable workload relief (NASA–Task Load Index [NASA-TLX]), nurse trust (validated human-robot interaction trust scales), and care quality indicators. No gate may be bypassed, and regression to an earlier gate is required if performance degrades at any stage. A formal multidisciplinary review, including nursing leadership, biomedical engineering, and safety officers, is required before advancing from Gate 3 to Gate 4. Within each gate, advancement is conditioned on predefined quantitative criteria of 2 kinds: absolute safety constraints that must not be violated, such as avoidance of collisions and unsafe proximity, and relative performance criteria benchmarked against acceptable task execution, such as task-completion accuracy and escalation appropriateness. Because the appropriate numeric thresholds depend on the task family, clinical unit, and risk profile, they are established and calibrated empirically during validation rather than fixed as universal constants at the conceptual stage; Multimedia Appendix 1 specifies the gate environments, evaluation-criteria categories, and nursing-relevant indicators against which these thresholds are set.

The conceptual reference architecture, including illustrative platform comparisons, sensor requirements, middleware integration logic, and a staged validation structure, is provided in Multimedia Appendix 1.

RenderX

Ethical, Professional, and Practice Implications

Governance should be built into the training pipeline from the outset, not retrofitted after technical development is complete. This means nurses should define the task library, escalation logic, and performance criteria, rather than only provide end-stage user feedback on systems designed without their input. The ethical stakes are significant: a robot operating in a clinical environment has the potential to affect patient safety, nurse workload, and the therapeutic relationship between nurse and patient. The framework addresses these stakes through several mechanisms. First, it preserves nurse authority over all ethically consequential decisions by design; the role-boundary map explicitly prohibits robotic action in domains requiring clinical judgment. Second, robotic support is bounded to clearly delegable task families where the consequences of error are manageable and reversible. Third, VR carries a governance function alongside its training function: it provides a predeployment space where action boundaries, error modes, and workflow consequences can be examined without risk to patients [5,6,24,25]. Fourth, the staged transfer gates embed ethical review into the development pipeline, ensuring that the decision to deploy a robot in a clinical unit is made by a multidisciplinary team, rather than by the technical development team alone. These design choices reflect a broader commitment to the principle that AI in nursing should augment professional practice rather than displace professional judgment [5,6].

Beyond these design commitments, 3 areas require explicit treatment because they condition whether such a system can be responsibly developed and deployed. The first concerns regulatory classification and legal responsibility. A learned policy that supports nursing tasks may, depending on its function and claims, fall within medical-device-software regulation, such as the US Food and Drug Administration framework for Software as a Medical Device [26,27], and, in other jurisdictions, within risk-based regimes such as the European Union Artificial Intelligence Act [28], both of which impose validation, documentation, and postdeployment monitoring obligations that a nursing robotics program must anticipate from the outset. Closely related is the allocation of liability when an autonomous system contributes to an adverse event: responsibility may be distributed among the nurse who supervises the system, the institution that deploys it, and the developer or manufacturer that builds it, and this distribution is not yet settled in law or policy. The framework does not resolve this question, but its retained human accountability, explicit role boundaries, and multidisciplinary sign-off at each transfer gate are designed to keep responsibility traceable rather than diffuse, providing an auditable record of who authorized what at each stage. The second and third areas concern data governance and patient consent. Nurse demonstrations, corrective feedback, and deployment logs generate behavioral and environmental data, and in a clinical setting this data may incidentally capture patient-related information; such data must be handled under institutional governance consistent with health-privacy law, including, in the United States, HIPAA-consistent deidentification and the exclusion of patient-identifiable information from training corpora. A distinct and less frequently acknowledged question is the ownership of and consent for the nurses' tacit expertise that the framework deliberately elicits and encodes, because the nurse-in-the-loop paradigm treats expert judgment as a primary training signal, the professionals whose knowledge is captured have a legitimate interest in how that knowledge is used, attributed, and governed. Finally, patients have an interest in robotic support operating in their care environment even when tasks are noncontact; institution-level notice-and-consent processes should make patients aware of robotic support and provide a means to decline it, preserving patient autonomy as a first-class consideration rather than an afterthought. Treating these regulatory, data-governance, and consent questions as design requirements, rather than as compliance steps addressed after development, is consistent with the framework's commitment to building governance into the pipeline from the outset.

Discussion

This paper repositions VR from a visualization tool to a translational training infrastructure connecting nursing expertise with robotic execution. The claim is not that nursing requires an entirely separate technological universe from big-tech physical AI; rather, nursing needs an additional nurse-centered orchestration layer that specifies workflow fit, role clarity, safety governance, and local adaptation as nonnegotiable adoption criteria. This complements the call by Shaw and Chen [3] for nursing-specific engagement with physical AI by providing a concrete architectural pathway from concept to implementation.

The 4-layer technical architecture grounds the framework in concrete implementation considerations. By specifying graphics processing unit–accelerated simulation, robotics middleware integration, staged imitation-to-reinforcement learning, foundation model backbones, uncertainty quantification, and staged transfer gates, the framework provides an implementation-aware roadmap that connects conceptual nursing robotics discourse with concrete implementation pathways. Each architectural layer addresses a specific translational challenge: layer 1 bridges the gap between clinical environments and simulation; layer 2 structures the learning process around nurse expertise rather than autonomous exploration; layer 3 embeds safety governance into real-time operation; and layer 4 enforces validation against nursing-relevant outcomes before any clinical contact occurs. This layered structure is intended to make the framework's plausibility conceptually arguable and incrementally verifiable through independently testable stages, rather than being assumed.

The strategic contribution is clarity of scope and sequence. Rather than proposing a generalized nursing humanoid—an aspiration that outpaces both current technology and clinical readiness—the framework defines a tractable developmental pathway: build a prototype VR environment for bounded supportive nursing tasks, test nurse-in-the-loop data collection and correction workflows, synchronize with one real clinical unit, and evaluate transfer against nursing-relevant outcomes. This incremental approach is more clinically defensible because it allows each stage to be independently validated and because

XSL•FO
RenderX

it confines early-stage risk to simulation rather than exposing patients or staff to insufficiently tested systems. It also aligns with how nursing practice itself manages complexity: through structured protocols, graduated responsibility, and continuous reassessment.

Several features distinguish this framework from existing approaches to health care robotics. Most current health care robots are developed outside nursing and offered to nurses as finished products; this framework places nurses at the center of the development process from task selection through policy training to transfer evaluation. Most simulation-to-real pipelines in robotics treat transfer as a technical challenge to be solved through domain randomization; this framework treats transfer as a governance event requiring nursing-relevant validation. Further, most health care digital twin implementations aspire to comprehensive hospital models; this framework adopts a pragmatically scoped twin constrained to variables that materially affect robotic task performance. These distinctions are not arbitrary; they follow from the recognition that nursing's requirements are not merely a subset of general robotics requirements but include qualitatively different demands around workflow integration, role clarity, and preserved professional authority.

This contrast is clearest when supportive autonomy is set against surgical autonomy. Surgical autonomy centers on contact-rich, submillimeter, and often irreversible manipulation of patient anatomy, which requires patient-specific high-fidelity modeling and fine force-level control. Supportive autonomy, as framed here, centers instead on logistical and environmental tasks whose errors are comparatively bounded and recoverable; where direct physical assistance is eventually introduced, it enters only under staged, nurse-governed validation gates rather than as the operating premise. This difference in kind is precisely why the framework's architectural choices fit supportive autonomy and would be insufficient for surgery: the pragmatically scoped digital twin, the workflow-centered and role-centered validation, and the gated transfer logic are calibrated to bounded support rather than to anatomical precision. What carries across domains is not the technical stack but the governance: expert-in-the-loop policy formation, staged validation, and retained human accountability are not specific to nursing and could inform surgical contexts, even though the fidelity and precision they must achieve differ fundamentally.

The framework also raises questions that warrant further investigation. How many expert nurse demonstrations are sufficient to train a robust foundation policy for a given task family? What is the minimum viable scope of a digital twin that preserves transfer validity? How should escalation thresholds be calibrated to balance safety against workflow disruption from excessive escalation? And how do nurses' trust and acceptance of robotic support evolve as they participate in the training process vs receiving a pretrained system? These are empirical questions that the framework is designed to enable rather than preemptively answer.

Limitations

Five limitations warrant explicit acknowledgment. First, this paper is conceptual and does not empirically test the framework; the proposed architecture is a structured hypothesis for future empirical validation. Second, the simulation-to-real gap remains incompletely solved. Sensor noise and clinical unpredictability will create transfer challenges that simulation cannot fully anticipate, and physical contact dynamics in particular—deformable-tissue interaction and subtle force modulation—fall outside the framework's initial noncontact scope and would require dedicated modeling and validation before any contact task could be approached. Accordingly, the transition from behavioral cloning to reinforcement learning is positioned not as a simulation step but as fine-tuning in the validated real environment: behavioral cloning establishes a safe foundation policy from expert demonstrations, while reinforcement-learning refinement is applied incrementally under the staged transfer gates rather than to anticipate contact dynamics in simulation. Multimedia Appendix 1 characterizes the principal dimensions of this transfer gap. Third, the digital twin literature remains technically immature in health care; implementers must calibrate expectations and adopt the pragmatic constraint recommended here. Fourth, hardware platform selection (autonomous mobile robot, cobot arm, and humanoid) will substantially shape which components are feasible and how the twin must be constructed. Fifth, although the framework places nurses at the center of robotic policy formation as a matter of design, this paper was itself developed through literature synthesis rather than through direct co-design with nurses, patients, or administrators. These are distinct levels of nurse centrality: positioning nurses as the authority who defines robotic scope is a property the framework specifies, whereas codeveloping that specification with practicing nurses is an empirical step the framework explicitly requires rather than one this conceptual paper performs. Accordingly, participatory co-design is not omitted but deferred as a core element of the next stage: future empirical work should begin with a participatory design phase in which nurses from the target clinical unit codevelop the task library, role-boundary map, and escalation logic before any VR environment is constructed. This sequencing—defining what nurses should govern at the conceptual stage and operationalizing that governance through participation next—resolves the apparent tension that the absence of co-design at this stage might otherwise suggest.

Future research should pursue several priorities. First, prototype VR environments should be constructed for specific bounded nursing task families, beginning with logistical tasks (supply transport and equipment retrieval) before advancing to more complex support tasks involving dynamic human interaction. Second, digital twin construction feasibility should be examined in real clinical units, including assessment of the time, cost, and institutional cooperation required to achieve adequate twin fidelity. Third, empirical studies should evaluate technical performance alongside nurse trust, workflow compatibility, and escalation quality, using mixed methods designs that combine quantitative performance metrics with qualitative analysis of nurses' experiences. Fourth, longitudinal studies should track

XSL•FO
RenderX

how nurse trust and acceptance evolve over repeated interactions with the training and deployment pipeline. Finally, cross-site generalization should be investigated: how much of the training pipeline transfers when the framework is applied to a different clinical unit with different geometry, workflow patterns, and nursing culture?

Conclusions

Physical AI in nursing should be framed as supportive robotics that reduce repetitive and physically burdensome work while preserving nurses' authority over judgment, prioritization, and relational care. This framing is not a concession to technological limitations; it is a principled design commitment grounded in what nursing is and what robots can meaningfully contribute to nursing practice in the near to medium term.

The nurse-in-the-loop, site-specific VR framework proposed in this paper addresses the current gap between conceptual promise and clinical feasibility through several integrated mechanisms. The task library and role-boundary map ensure that the robotic scope is defined by clinical judgment rather than technical capability. Nurse-in-the-loop VR training ensures that the robot's learned policies reflect expert nursing knowledge, contextual awareness, and safety priorities. Progressive simulation fidelity structures the learning process to build competence incrementally, avoiding premature exposure to clinical complexity. Site-specific digital twin synchronization bridges the gap between generic simulation and the particular physical and organizational realities of the deployment environment. Governed simulation-to-real transfer ensures that advancement from simulation to physical deployment is conditioned on explicit nursing-relevant validation criteria, with human accountability retained at every stage.

Taken together, these elements constitute a translational infrastructure rather than a single technological intervention. VR is not merely a visual training aid in this framework; it is the environment where nursing expertise is elicited, structured, annotated, stress-tested, and safely transferred to physical systems. The digital twin is not a visualization tool; it is the mechanism through which generic robot capabilities are adapted to local clinical realities. Further, the nurse is not an end user to be consulted after development; the nurse is the domain expert whose knowledge, judgment, and workflow requirements drive the entire pipeline.

This framework contributes to nursing informatics by proposing a concrete mechanism through which nursing knowledge can be formally structured and transmitted to physical AI systems, extending the discipline's engagement with AI beyond decision support and documentation into the domain of embodied, physically acting systems. It contributes to robotics by articulating a domain-specific orchestration layer that connects general-purpose physical AI capabilities with the particular requirements of a complex, safety-critical, and human-centered work environment. It also contributes to patient safety by ensuring that the path from simulation to clinical deployment is governed by explicit criteria, staged validation, and retained human authority.

The path forward requires sustained collaboration between nursing scientists, robotics engineers, clinical administrators, and the nurses who ultimately work alongside these systems. The framework proposed here is intended as a structured starting point for that collaboration—not a finished system, but a principled architecture within which empirical questions can be posed, tested, and iteratively refined.

Abstract

The global nursing workforce crisis demands a shift from reactive staffing to strategic workforce optimization through data-driven decision-support systems. This viewpoint paper reflects on the development and attempted implementation of the balanced nursing teams system, a decision-support tool integrating approximately 250 data points—of which roughly 150 are extracted from existing organizational systems (human resources, scheduling, electronic health records, quality registries) through flexible import mechanisms, and the remainder collected through a built-in 360-degree staff survey with automated analysis—across 10 domains to evaluate nursing team balance between capacity, performance, and outcomes. Following crowdfunding by 18 Belgian health care organizations, balanced nursing teams were implemented across 8 diverse settings (home health care, general hospitals, academic centers) between 2019 and 2023. Using the Human-Organization-Technology fit framework, we analyze why evidence-informed, organization-endorsed digital innovations struggle to achieve adoption. Our analysis reveals 3 interdependent barrier categories: technological fragmentation (vendor lock-in, legacy systems, prohibitive integration costs), organizational siloing (Chief Nursing Officers [CNOs] lacking budgetary authority, nursing framed as peripheral to strategic priorities), and managerial hesitance (fear of punitive data use, cognitive overload from staffing crises). These barriers were worsened by the substantial data-integration burden that the system's breadth imposed on organizations with limited digital maturity. Critically, only one site (ie, a nurse-led home health care organization where leadership held both strategic authority and resource control) achieved sustained implementation. This contrast demonstrates that workforce optimization through data depends not on software maturity alone, but on achieving simultaneous fit across human, organizational, and technological domains. We argue that the persistent marginalization of nursing leadership within hospital governance structures represents the fundamental barrier to digital transformation in nursing workforce management. The urgency paradox is striking: while nursing represents health care organizations' highest operational cost and most direct patient interface, workforce optimization tools are consistently deprioritized in favor of regulatory compliance systems and billing infrastructure. Bridging this gap requires systemic investment in nursing leadership authority, data interoperability standards, and recognition that data-driven workforce decisions are strategic imperatives rather than operational luxuries.

Introduction

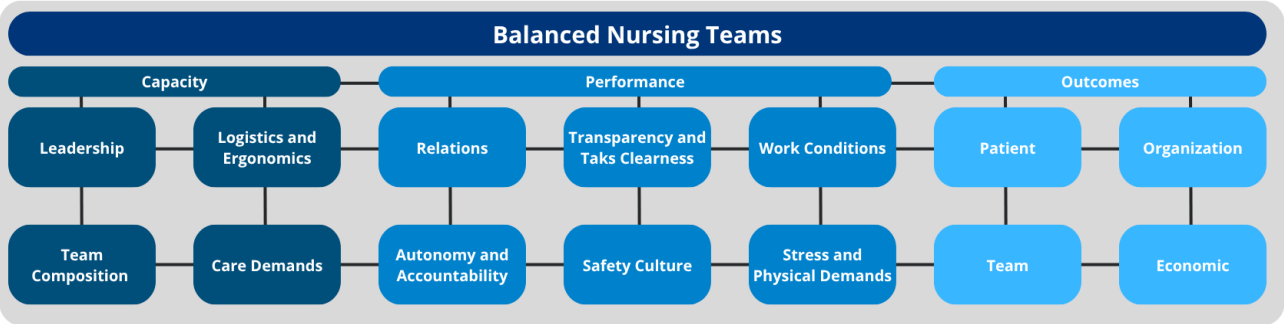
Overview

The global nursing workforce crisis extends beyond simple shortages. Persistent mismatches between staffing levels, skill mix, and patient demand have been linked to missed care, adverse outcomes, and failure to rescue, ultimately compromising both patient and staff outcomes [1-4]. While policymakers have focused primarily on increasing the number of nurses entering the workforce, evidence indicates that expanding supply alone does not resolve the underlying staffing challenges [5,6]. The retention of experienced nurses depends on the work environment quality and team performance [7], yet high turnover continues to impose substantial financial and operational burdens on health care organizations [8].

Current staffing models, such as mandatory nurse-to-patient ratios, fail to capture the complexity of nursing team dynamics, skill mix optimization, and broader contextual factors that

XSL•FO
RenderX

determine whether care teams can effectively meet patient demands [9]. Addressing this challenge requires a shift from ratio-based workforce planning towards data-informed team design that integrates human, organizational, and contextual dimensions of nursing care [9].



This viewpoint paper offers a critical reflection on the sociotechnical challenges of implementing digital workforce innovation in nursing. Drawing from our experience developing and testing the balanced nursing teams (BNuT) decision-support system across 8 Belgian health care organizations, we examine why evidence-informed, practitioner-endorsed digital tools struggle to achieve real-world adoption. Rather than presenting a traditional implementation study, we provide an analytical perspective on the systemic barriers that constrain digital transformation in nursing workforce management, offering lessons for researchers, health care organizations, and policymakers pursuing similar innovations.

A Nursing Teams Composition and Staffing Decision-Support System: BNuT

In response to these challenges, the BNuT initiative was launched in 2018 through a collaboration between a member organization of Belgian health care organizations and 2 research groups. The project originated from a clear practical demand: develop an instrument that enables evidence-based, proactive, and data-driven decisions regarding nursing team composition. Following proof-of-concept development, 18 health care institutions collectively crowdfunded the project, reflecting broad recognition of this critical gap in nursing workforce management.

BNuT was conceived as a computerized decision-support instrument designed to optimize team composition and team functioning in ways that existing tools cannot. While most workforce software estimates patient demand or calculates staffing levels based on mandatory ratios [10], these systems rely heavily on manual governance and contextual adjustment. In contrast, BNuT integrates data across multiple domains—including relational dynamics, autonomy, care demand, leadership, logistics, and safety—into a unified team-level model of workforce balance (Figure 1).

Figure 1. Conceptual model of the balanced nursing teams (BNuT) system. The figure depicts the 10 subcomponents supporting the BNuT decision-support system, organized into 2 overarching categories: capacity domains (team composition, care demands, staffing, and skill mix) and performance domains (leadership, logistics, safety culture, workload distribution, team dynamics, and professional development). These domains collectively inform the assessment of team balance, ranging from negative imbalance through optimal balance to positive imbalance.

The system estimates team balance on a continuum ranging from negative imbalance (eg, excessive workload and high risk of burnout) through optimal balance to positive imbalance (eg, over-capacitated teams and high risk of boreout). This continuum builds on earlier conceptualization of a balanced care team as one in which capacity, including care demands and team composition (4 domains) and operational performance processes (6 domains), is strategically aligned to optimize outcomes for both staff and patients, as well as organizational and economic outcomes [9]. Sustained imbalance between the 10 domains undermines both care quality and workforce sustainability. BNuT aims to operationalize this principle by assessing the alignment between nursing workforce organization and patient care needs, translating complex multidimensional data into actionable, evidence-based visual indicators for team and managerial decision-making.

The development of BNuT followed a staged approach designed to progressively establish validity and relevance. The underlying model was empirically grounded in a systematic scoping review that identified 35 factors across 9 domains of balanced team functioning [9]. The indicator set was subsequently refined through structured codevelopment with nursing managers from participating institutions, who assessed each variable's clinical importance, data availability, and interpretive complexity. The application itself was co-designed with end users through user-story workshops that shaped functionality, interface design, and workflow integration. This iterative process established content validity, ensured practical relevance, and confirmed usability. However, criterion validation against patient and staff outcomes, which was originally planned via the operational deployment in participating hospitals, could not be completed. This validation gap was caused by the sociotechnical barriers described in this paper, as they prevented the successful implementation necessary for outcome evaluation. BNuT should therefore be understood as a theoretically and empirically informed decision-support prototype. Its outcome validation remains contingent on achieving the organizational conditions for sustained use.

Aim and Analytical Framework

This paper provides a reflective analysis of the sociotechnical challenges encountered during the development and testing of BNuT. We move beyond technical specifications to examine

XSL•FO
RenderX

why digital innovations supported by both evidence and organizational demand struggle to achieve real-world adoption. Our analysis uses the Human-Organization-Technology fit (HOT-fit) framework [11], a model specifically developed for evaluating health information systems. This framework maps the 3 principal barrier categories observed in our work and highlights how interactions among human, organizational, and technological factors jointly shape implementation outcomes. Each dimension is examined systematically, followed by an integrative reflection demonstrating how compounding barriers can obstruct implementation even when individual system components function as designed. This viewpoint does not present outcome validation of the BNuT system; rather, it offers a structured reflective analysis of implementation dynamics, informed by 8 years of engagement with participating organizations and stakeholders across the Belgian health care field.

The insights presented in this viewpoint are grounded in 8 years of sustained engagement with the BNuT project (2018 - 2026), encompassing the full cycle from conceptualization and codevelopment to attempted implementation across 18 health care institutions. During this period, the author team engaged in extensive, iterative dialogues with stakeholders across all levels of the health care system (eg, frontline nurses, nursing managers, CNOs, data managers, data protection officers, IT departments, and external development partners) through codevelopment workshops, pilot testing sessions, steering committee meetings, and formal presentations to prospective adopters and investors. Each of these interactions generated feedback that progressively shaped the team's understanding of the barriers and enablers discussed in this paper. The reflections synthesized here emerged iteratively from this long-term, multi-stakeholder engagement. This approach prioritizes ecological breadth and depth of immersion over the rigor of structured qualitative research. The HOT-fit framework [11] was applied retrospectively to organize and analyze these accumulated insights, providing an analytical foundation.

The BNuT System and Implementation Context

BNuT Concept and Architecture

Health care organizations face a fundamental data paradox in nursing workforce management. While data seems abundant, the information remains siloed across systems, leaving leaders without the integrated insight required for strategic workforce decisions. Existing information systems were primarily designed for billing and regulatory compliance rather than operational or strategic decision-making. As a result, critical data concerning team dynamics, workload distribution, competency mix, and patient demand remain fragmented across incompatible platforms, such as electronic health records (EHRs), scheduling tools, human resources (HR) databases, and quality registries. This fragmentation and the lack of comprehensive data warehouses or business intelligence tools leave nurse managers operating largely reactively, addressing daily staffing shortages without insight into long-term workforce patterns or their impact on safety, quality, and retention. Moreover, staff lack a data-informed understanding of their team capacity, performance, and outcomes, and must rely largely on perceptions. This data paradox has become increasingly consequential as contemporary health care systems face mounting pressures: cost containment imperatives, heightened quality and safety demands, and growing clinical hyperspecialization that requires more sophisticated approaches to team composition and skill-mix optimization.

BNuT aims to address these challenges through 2 interconnected objectives that shift workforce management from reactive to strategic. The first involves comprehensive data collection and processing to enable both cross-sectional analyses (capturing current team states) and longitudinal tracking (monitoring team evolution). This supports standardized decision-making capable of distinguishing between expected variance, acceptable fluctuations, and disruptive imbalances. The second objective focuses on integrating multiple data streams into meaningful composite indicators at the clinical microsystem level, encompassing workload intensity, competency distribution, leadership effectiveness, safety climate, and related domains to estimate the balance between team capacity, performance and care demands, and outcomes.

To achieve this, the system combines a 360-degree evidence-based survey, capturing staff perceptions on statements within each capacity and performance domain, and data drawn from existing organizational systems such as scheduling software, EHRs, and quality metrics. All data are synthesized using established evidence-based standards in nursing workforce research, ensuring that the resulting indicators reflect empirically supported relationships between the domains. Crucially, the unit of analysis is the clinical microsystem, acknowledging that patient and team outcomes emerge from collective team processes rather than individual performance metrics. The system supports dynamic management through continuous monitoring and benchmarking functions, allowing leaders to compare performance across teams, identify high-performing configurations, and support continuous improvement. Team involvement in discussing these data is paramount to support teams and leaders in understanding team strengths and weaknesses, to identify improvement priorities, and to assess the extent of readiness for innovation [12]. BNuT thus provides managers and leadership with both a helicopter view for strategic oversight and the ability to zoom in on specific teams or metrics when deeper investigation is required, thereby supporting decision-making at operational, tactical, and strategic levels.

Implementation Setting and Challenges

BNuT was implemented across 8 health care organizations representing diverse contexts, including home health care, general hospitals, and academic centers. Although the degree of adoption varied, each site revealed distinct yet interrelated sociotechnical barriers that influenced feasibility and uptake:

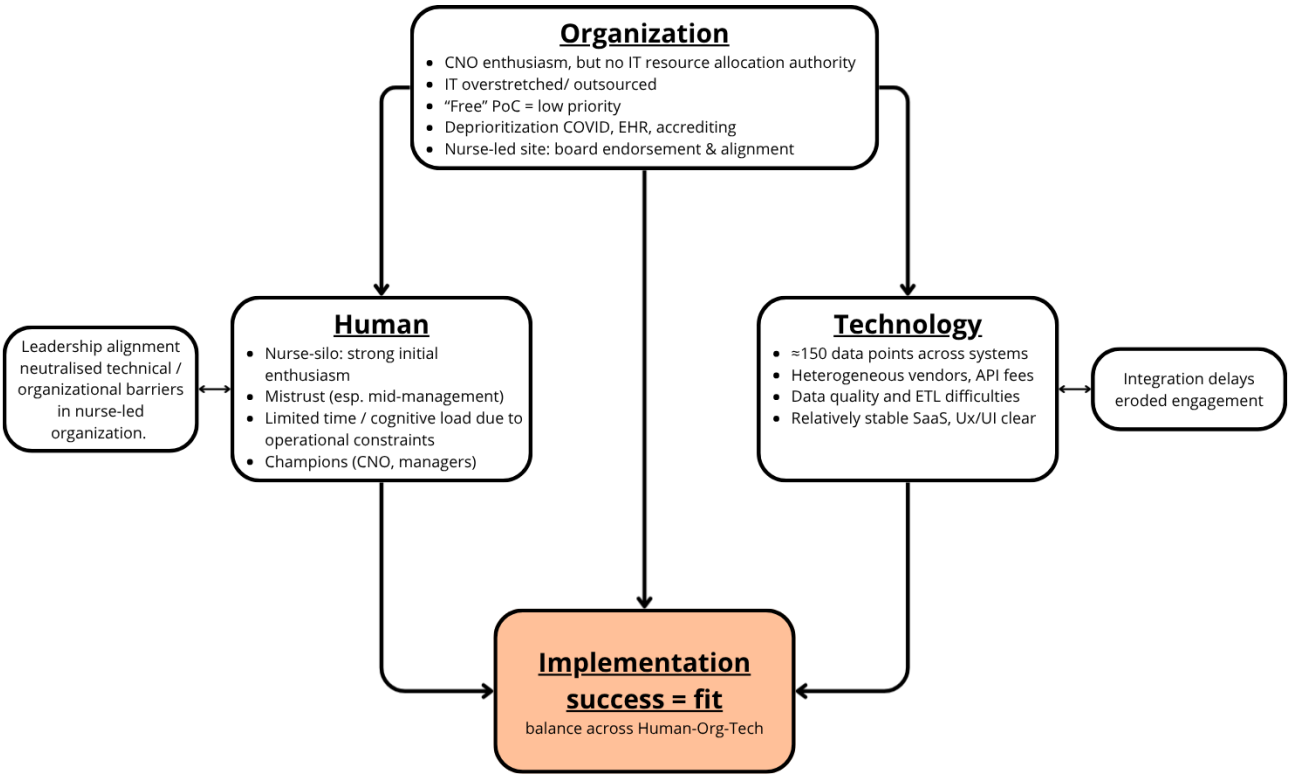
1. At the human level, hesitance and abstention emerged as key barriers. While these responses may originate as reactions to perceived risks, the resulting behavioral patterns—reluctance to engage, delayed adoption, or outright avoidance—function as implementation barriers. Nursing leaders and managers expressed concern that

XSL•FO
RenderX

BNuT-generated insights might be misused in their performance evaluations. There was also apprehension about receiving feedback without having the resources or organizational support to act on it, creating a sense of accountability without agency. The operational pressures of managing day-to-day staffing crises left little cognitive bandwidth for strategic workforce optimization. This environment discouraged engagement with reflective data tools, despite general support for the underlying vision.

2. At the organizational level, siloed priorities and hierarchical governance structures undermined implementation. Financial executives, facing severe budget constraints (particularly relevant given that approximately 40% of Belgian hospitals operate at a financial loss [13,14], perceived workforce optimization tools as an additional cost rather than an investment. Chief technology officers, while conceptually supportive, found it difficult to justify allocating scarce IT resources to early-stage, nurse-led projects lacking immediate financial return. This division between nursing leadership (operational authority) and executive governance (strategic control) created a structural misalignment that limited implementation feasibility.
3. At the technological level, integration of existing systems proved prohibitively complex and expensive due to vendor lock-in strategies, legacy system fragmentation, and deliberate data walling between platforms. Several hospitals had outsourced IT operations, transforming what could have been internal configuration tasks into costly external service requests requiring formal budget approval. IT departments, already constrained by workforce shortages and competing project portfolios, often struggled to prioritize nurse-led digital innovations.

Out of the 8 health care organizations, one site achieved substantial success offering a contrasting perspective. Operating as a nurse-led home health organization, its leadership culture embedded the vision of data-driven workforce optimization from the outset. Alignment between operational need, executive vision, and organizational authority enabled integration of BNuT into management routines. This contrast underscores the critical role of organizational alignment and leadership ownership in realizing the potential of sociotechnical innovations such as BNuT.



The 3 Dimensions of Barriers

Identifying the HOT-Fit

The implementation experiences of the BNuT project were examined through the HOT-fit framework [11]. The framework provides a sociotechnical lens for analyzing how system adoption and sustainability depend on the alignment, or fit, between 3 interacting domains: human, organizational, and technological. Our reflections demonstrate that BNuT's implementation challenges were not isolated to any single dimension. Rather, success depended on achieving an equilibrium across domains, and an imbalance in one frequently undermined progress in the others (Figure 2). This section reflects on lessons learned within each domain and concludes by considering the interdomain dynamics that shaped implementation outcomes.

XSL•FO
RenderX

Figure 2. HOT-fit framework applied to the BNuT implementation. The diagram illustrates the 3 interacting domains of the HOT-fit model and their relationships in the context of the BNuT decision-support system. Arrows represent interdependencies: successful implementation (fit) occurs only when all domains are simultaneously aligned. Callouts highlight two key observations: (1) strong fit within the organizational domain—where nursing leadership held both strategic authority and operational responsibility—enabled the nurse-led organization to overcome technical barriers, and (2) data-integration delays eroded user engagement. API: application programming interface; BNuT: balanced nursing teams; CNO: chief nursing officer; EHR: electronic health record; ETL: extract-transform-load; HOT: Human-Organization-Technology; PoC: proof of concept; SaaS: software-as-a-service; UX/UI: user experience/user interface.

Human: Trust, Empowerment, and Cognitive Capacity

Across the participating organizations, nursing leaders were consistently enthusiastic about BNuT's conceptual promise. The idea of a data-driven instrument capable of translating complex workforce information into actionable team-level insights resonated strongly with their daily struggles. Notably, the project itself originated from nursing leaders' explicit requests for better decision support tools, making BNuT a response to practitioner demand rather than a top-down research initiative. Early skepticism during prototype demonstrations largely dissipated once realistic use cases were presented. The urgency of developing such a system was widely acknowledged, and many leaders expressed relief that a project finally addressed the persistent gap between workforce research and managerial decision support.

> *The added value that this tool will be able to give us in the future was clear to everyone in the meeting. It will enable us to make an in-depth analysis based on objective data about the functioning of a team and also indicate on which elements action is required to remedy this.* [Chief Nursing Officer, participating hospital]

> *BNuT provides a most powerful lens for every nurse manager. Gain personal leadership and team insights to transform your department with data-driven decisions for better care and satisfied staff.* [Nurse Manager involved in BNuT pilot testing]

However, this enthusiasm coexisted with overconfidence regarding implementation feasibility. Many nursing leaders underestimated the organizational and technical barriers involved and overestimated their own authority to overcome them. Hospitals with advanced data infrastructures were paradoxically more hesitant, perceiving BNuT as "yet another system" rather than as a complement to existing business-intelligence tools. These organizations typically requested an Application Programming Interface (API) to integrate BNuT's algorithms into their own dashboards rather than adopting the full platform. Conversely, smaller organizations, particularly those without internal analytics capacity, perceived BNuT as uniquely valuable but lacked the resources to integrate it.

Hesitance surrounding data use proved a recurrent issue, though its nature differed markedly across organizational levels. Among frontline nurses, concerns were minimal once the survey's anonymity was assured; they generally perceived BNuT as a supportive and developmental tool rather than a threat. In contrast, hesitance and some mistrust were concentrated among junior and mid-level managers, who feared that aggregated results, particularly those reflecting leadership climate or organizational support, could be interpreted punitively by higher management. In one large university hospital, even the CNO voiced concern that unfavorable scores on "organizational leadership" might be politically exploited by other executives. These perceptions reveal the asymmetrical distribution of vulnerability within hierarchical hospital structures: while staff

XSL•FO
RenderX

trusted the system's safeguards, middle management occupied a position where performance data could plausibly affect professional standing.

Demonstrations and early pilots substantially increased perceived usefulness. Once users saw how disparate data streams converged into interpretable insights, engagement improved markedly. A frequently cited example involved incident reporting: one team appeared to have a disproportionately high number of reported safety incidents. Initially interpreted as poor performance, the BNuT analysis revealed that this team simultaneously scored highest on safety culture, indicating a healthy incidence-reporting climate. Such cases illustrated how integrated data interpretation could challenge misperceptions and reframe organizational learning.

Despite these successes, cognitive and temporal constraints limited sustained engagement. Nursing managers facing chronic staffing shortages and operational crises had little time to interact with a strategic-level dashboard. The tool's intuitive design mitigated digital-literacy barriers, yet the absence of formal onboarding and the overall cognitive load of crisis management restricted deeper adoption. Champions, typically CNOs or middle managers, emerged in nearly all sites, but their influence was constrained by limited institutional authority. Over time, enthusiasm at the human level could not compensate for systemic resource constraints and organizational inertia.

However, it must also be acknowledged that the system's own scope likely contributed to the cognitive and governance burden experienced by potential adopters. BNuT encompasses 10 domains and integrates approximately 250 data points, of which roughly 150 are to be extracted from organizational systems. While the user-facing interface was specifically designed to simplify interpretation by reducing this complexity to composite indicators and visual summaries, the underlying data requirements imposed demands on organizational processes that were substantial, particularly for institutions already operating under severe resource constraints. For organizations with limited digital maturity, the gap between the system's data needs and the institution's capacity to deliver that data may have been too large, regardless of the tool's analytical value. In retrospect, a more modular deployment strategy might have lowered the threshold for initial adoption: beginning with a reduced core indicator set drawn from readily available data and progressively activating additional domains as organizational data capacity matured would have allowed trust, familiarity, and demonstrable value to develop incrementally before the full model was introduced.

Organizational: Leadership Alignment and Structural Inertia

The organizational context proved decisive. In all hospitals, the CNOs were strong advocates for BNuT, yet they lacked budgetary control. IT departments, already overstretched and managing numerous competing projects, had to allocate technical resources, while financial decisions ultimately rested with chief financial officers. Because the project was offered free of charge during the proof-of-concept phase, it competed poorly for attention against commercial initiatives with contractual obligations. In hindsight, requesting a modest financial buy-in might have enhanced commitment and prioritization by signaling ownership.

Both HR and IT departments often viewed BNuT as redundant. HR staff perceived it as encroaching on their existing tools, while IT departments regarded it as a low-priority research experiment. Chronic shortages of IT personnel further reduced their willingness to support time-consuming integrations. In several hospitals, IT services had been partially outsourced, transforming even minor configuration tasks into expensive external contracts. In some cases, hospitals lacked in-house capacity to access their own databases, as software vendors maintained exclusive control and charged high fees for basic queries. These arrangements effectively held data "hostage" and created a very high dependency on vendors for data extraction.

Organizational fit, the degree to which nursing leadership held authority corresponding with operational responsibility, emerged as the critical differentiator. In hierarchical organizations where the nursing department functioned as a silo, CNOs struggled to gain board-level approval. Projects framed as nurse-led were perceived as peripheral to strategic objectives. By contrast, the one nurse-led organization integrated BNuT into its formal strategic plan, supported by executive leadership and dedicated IT allocation. This fit between operational need, strategic vision, and resource authority was essential. It enabled the project to progress from conceptualization to sustained use, highlighting the necessity of structural empowerment for nursing leadership within governance systems.

> *We use BNuT as an integrated data and communication system in our organization to better understand our practices and outcomes in home health and to lead and manage our organization proactively.* [CEO Home Health Organization]

Competing institutional priorities further hindered progress. Post-COVID recovery, ongoing EHR upgrades, and accreditation audits absorbed most organizational attention. Because BNuT did not have immediate regulatory or financial implications, it was consistently deprioritized. Organizational culture also played a role: hospitals with participatory cultures tended to show greater openness to collaboration, whereas highly hierarchical institutions rarely progressed beyond exploratory discussions. Overall, BNuT's organizational challenges reflected the entrenched marginalization of nursing leadership within hospital governance, a systemic issue that extends beyond this specific innovation.

Technological: Interoperability, Data Quality, and Usability

The technological domain presented the most concrete and persistent barriers. BNuT requires integration of about 250 data points, where approximately 150 data points can be drawn from existing systems: HRs, scheduling, EHRs, quality registries, and even locally maintained spreadsheets. Each organization used a unique constellation of software vendors and data formats, often without shared standards. Even when multiple hospitals used the same vendor, integration had to be redeveloped from scratch due to licensing and cost restrictions.

XSL•FO
RenderX

Vendors frequently imposed additional charges for API access or custom data exports, and in several cases claimed that bespoke queries were required for every new request.

Manual preprocessing was initially necessary to conform to the BNuT data structure. Anticipating this challenge, the system was designed with a flexible, tiered integration architecture: organizations could upload data manually per data point through the web interface, push standardized files through an automated importer in an agreed-upon format, or connect directly to a PostgreSQL database structure into which raw data could be pushed with automated ETL processing. To further reduce this burden, the project contracted an external ETL specialist who configured direct connections to source systems where feasible. Despite this flexibility, the approach proved only partially effective due to heterogeneous database architectures, limited vendor documentation, and the cost of obtaining data exports from third-party software providers. Data quality issues were widespread: implausible values were common, and missingness varied widely between datasets. BNuT's algorithms were designed to tolerate partial missingness, except for a few core variables essential for standardization, but the variability still limited analytic robustness. The persistence of these barriers, even given the system's deliberately flexible architecture, underscores that the bottleneck was structural and rooted in vendor lock-in, fragmented data governance, and limited hospital IT capacity.

Despite these integration difficulties, the user-facing technology was well received. A professional user experience/user interface designer ensured that the interface was intuitive and visually clear, with a simplified radar chart summarizing 10 domains of team performance. Users could benchmark teams or explore subdomains with minimal training. The system was web-based (Software as a Service) and accessible through standard browsers, providing sufficient performance and stability for managerial use.

Maintenance and updates were provided by the research team in collaboration with a contracted developer. Hospitals were able to independently distribute surveys and upload local data, and feedback loops for technical improvement remained informal. Overall, the technical obstacles were concentrated in data extraction and integration rather than in software usability or performance.

A critical question arising from the BNuT experience is whether a model integrating approximately 250 data points was over-engineered. The breadth of the model reflects our conceptual ambition of capturing team balance across all domains identified as relevant in the empirical literature [9], an ambition that was codeveloped and endorsed by the participating organizations themselves. However, the practical consequence was a data-governance burden that exceeded the current capacity of most hospital sites, particularly those reliant on legacy systems, outsourced IT functions, or fragmented data architectures. Even the flexible integration mechanisms provided could not overcome the structural barriers imposed by vendor lock-in and the cost of data extraction from proprietary systems. This tension between comprehensiveness and feasibility represents a design challenge that is not unique to BNuT but characterizes many health information systems that attempt to bridge the gap between research-level measurement and operational reality [15]. Future iterations of such systems should consider adopting a modular architecture where a core set of indicators (operationalizable with minimal integration effort and immediately actionable for nursing managers) serves as the entry point, while the full model is reserved for organizations with sufficient digital infrastructure and data-governance capacity.

Interdomain Fit: A Prerequisite for Sustainability

Analysis across HOT-fit domains highlights that implementation success depended on achieving simultaneous fit across all 3 dimensions. The nurse-led organization illustrated how a strong fit within the organizational domain, where nursing leadership held both strategic authority and resource control, could compensate for barriers in other areas. Once executive endorsement was secured, IT resources were allocated, data-sharing agreements expedited, and BNuT was embedded in strategic planning. The same technical hurdles that halted progress elsewhere became manageable. Conversely, where one domain lacked fit, most commonly technology, momentum in the others dissipated.

In several hospitals, delays in data integration eroded enthusiasm among nursing leaders who initially championed the tool. Similarly, where organizational structures prevented nursing leadership from influencing IT or financial decisions, human-level motivation could not translate into implementation capacity. Positive feedback loops only emerged when success was visible and endorsed from the top: early demonstrable value encouraged further engagement and resource allocation, but such cycles remained rare.

Overall, these patterns confirm the HOT-fit framework's central proposition: the effectiveness of health information systems depends not merely on the functionality of individual components but on the equilibrium between them. Imbalance in any single domain propagates across the system, undermining overall fit. In BNuT's case, technological constraints, particularly data integration and interoperability, acted as the principal bottleneck, yet organizational and cultural dynamics determined whether these constraints could be overcome. Strong leadership endorsement, clear strategic positioning of nursing within governance structures, and proactive attention to data-trust and communication dynamics proved essential conditions for sustaining progress. The nurse-led success case offers a critical insight: when nursing leadership holds both strategic authority and operational responsibility, implementation becomes feasible. In this organization, the same technical challenges that stalled progress elsewhere were systematically addressed because nursing leadership could directly allocate resources, prioritize IT projects, and embed BNuT within strategic planning. This demonstrates that the barriers encountered elsewhere were not primarily technical but organizational. Conversely, when nursing remains positioned as a cost-center with limited influence over budgets and technology decisions, even technically sound innovations may struggle to take root. Achieving fit across human, organizational, and technological systems is therefore not only a condition for

XSL•FO
RenderX

digital success but also a reflection of the broader power balance between clinical professions and institutional structures within health care.

Discussion

Principal Findings

The main finding of this reflective analysis is that the implementation of BNuT succeeded only where simultaneous alignment across human, organizational, and technological domains was achieved, specifically in a nurse-led home health organization where leadership held both strategic vision and budgetary authority. Across the 7 hospital sites, adoption was prevented by converging barriers: data interoperability failures driven by vendor lock-in and fragmented IT architectures, restricted nursing leadership authority within hierarchical governance structures, and the substantial data-governance demands imposed by the system's own breadth. These findings are not unique to the Belgian context but reflect structural dynamics widely documented in health informatics.

More specifically, the BNuT implementation illustrates how organizational complexity constrains decision-support adoption in nursing practice. Across sites, barriers arose primarily from misalignment between human, organizational, and technological domains, although BNuT's own data requirements may also have exceeded the digital capacity of participating institutions. This finding echoes long-standing observations within implementation science that the success of health information technology depends less on technical soundness than on contextual fit within existing workflows, governance, and professional cultures [16].

The predominance of technological barriers parallels systematic reviews showing that interoperability failures remain the most persistent obstacle to decision-support integration [17,18]. As in those studies, the inability to access or standardize data across HR, scheduling, and clinical systems eroded perceived reliability and constrained analytic capability. These "barriers of insufficiency" [17] reflect structural deficits in hospital IT resourcing rather than isolated project limitations, reinforcing the need for policy-level interoperability mandates.

The vendor lock-in and data fragmentation observed in the BNuT project are not isolated to the Belgian health care context. Internationally, similar dynamics have been extensively documented. In England, the National Programme for IT (NPfIT) was ultimately dismantled in 2011, in part because of vendor lock-in and the inability to achieve interoperability across hospital trusts [19,20]. Subsequent NHS strategies have mandated open standards and fast health care interoperability resources–based interoperability, yet in practice, vendor-controlled data architectures continue to impede secondary use of clinical and workforce data [21-23]. In the United States, the 21st Century Cures Act introduced explicit information-blocking provisions to prevent vendors from restricting data access, reflecting federal recognition that proprietary data practices constitute a systemic barrier to innovation [24]. Within the European Union, the proposed European Health Data Space regulation represents an emerging attempt to establish cross-border interoperability standards that could, in principle, reduce the per-project negotiation costs that proved limiting in the BNuT experience [25]. Collectively, these international examples confirm that the barriers encountered by BNuT reflect a structural problem in health IT governance, and that no amount of tool-level design can compensate when system-level interoperability standards are absent.

At the organizational level, the imbalance between nursing leadership enthusiasm and restricted resource authority emerged as decisive. BNuT encountered resistance not from overt opposition but from structural dependency on nonclinical decision-makers, reflecting what has been described as the "negotiation of control" in health care technology implementation [26]. When nursing leaders lacked access to financial or technical levers, implementation stalled despite clinical support [27]. This pattern may reflect broader international challenges: research suggests that even within integrated health systems, resource allocation and workflow redesign remain chronic bottlenecks [28], while CNO authority limitations and IT resource allocation challenges appear to be documented across health care systems globally [17,27]. The single nurse-led organization in our sample, where strategic and budgetary authority were unified under nursing leadership, achieved full operational use, empirically supporting the HOT-fit premise that fit across all domains is a prerequisite for sustainability.

The human dimension was characterized by enthusiasm to hesitation, abstention to mistrust. Nurses did not resist technology per se, but distrusted implementations perceived as top-down or evaluative [29]. The anonymity of BNuT's survey component mitigated some of these concerns, yet lingering fears of data misuse illustrate fragile power dynamics [26]. Time pressure and cognitive overload further limited engagement, with research showing that human-resource scarcity continues to undermine even well-designed interventions [17].

Taken together, our findings reinforce the view of health care organizations as complex adaptive systems in which technical, organizational, and human subsystems are tightly coupled [16]. Localized improvements in one domain cannot compensate for deficits in another. The nurse-led success case exemplifies this interdependence: strong executive sponsorship overcame technical and organizational inertia, producing a functioning sociotechnical equilibrium. In contrast, sites lacking such fit experienced cascading failure: data integration delays reduced managerial trust, which in turn decreased organizational priority. Implementation success thus required "all lights green," confirming HOT-fit's central premise that sustainable adoption depends on balanced interaction across domains.

The conceptual contribution of BNuT lies in extending decision support beyond patient-level staffing ratios towards team-level optimization, incorporating leadership, workload, and safety culture. This holistic approach addresses gaps identified in recent reviews of nursing decision-support systems, which report limited theoretical grounding and minimal postimplementation evaluation [30]. Yet the difficulties experienced in this project also underscore the persistent divide between research prototypes and operational systems. Bridging this divide will

XSL•FO
RenderX

require not only improved technical integration but also structural empowerment of nursing leadership to act as equal partners in digital transformation.

The lessons from BNuT have concrete implications for the design of future nursing decision-support systems. First, scalability demands a shift from monolithic, all-or-nothing deployment towards modular architectures that allow organizations to adopt core functionality with minimal integration effort and progressively expand as digital maturity grows. An API-first, cloud-native design would reduce per-site configuration costs and enable integration with diverse IT ecosystems without requiring bespoke development for each vendor. Second, adaptability requires that indicator sets are configurable to organizational context: rather than imposing a fixed 250-variable model, future systems should allow institutions to select domains aligned with their strategic priorities and data availability, with the full model serving as an aspirational benchmark. Third, integrating predictive analytics, for example, flagging units where scheduled team composition falls below stability thresholds, or forecasting turnover risk based on employment pattern trends, would shift such tools from retrospective reporting towards prospective decision support, increasing their value for both unit-level workforce management and organization-wide strategic planning. Fourth, interoperability should be embedded by design rather than retrofitted: adopting open data standards and European Health Data Space–compatible data models from the outset would reduce dependency on vendor-specific export mechanisms. For clinical data, standards such as HL7 fast health care interoperability resources provide a foundation; however, workforce-specific data (including turnover, employment patterns, and team composition metrics) are not yet covered by existing interoperability standards, highlighting the need for standardized data models for nursing workforce analytics as a prerequisite for tools like BNuT.

Taken together, the findings demonstrate that sustainable digital innovation in health care depends on achieving fit across human, organizational, and technological systems. Where one domain fails, whether through technical fragmentation, limited leadership authority, or mistrust, momentum across the others may diminish. Conversely, fit across all domains enables small successes to compound into sustained adoption.

Furthermore, they reveal a troubling urgency paradox. Given mounting workforce shortages, cost pressures, and quality demands, strategic optimization of nursing team deployment should arguably be among health care organizations' highest priorities. The nursing workforce represents both the highest operational cost and the most direct interface between an organization and its patients. Yet across the sites studied, workforce optimization tools were consistently deprioritized in favor of regulatory compliance systems, billing infrastructure, or projects with more immediate financial returns. This misalignment between stated workforce priorities and actual resource allocation warrants attention from nursing leadership and policymakers alike. Translating these insights into practice yields several actionable lessons for the key stakeholders shaping the future of the nursing workforce.

Several limitations of this viewpoint must be acknowledged. First, the authors were the developers of BNuT, which creates an inherent risk of presenting the tool more favorably than an independent analysis might. We have tried to apply a self-critical lens, particularly in examining whether the system's own complexity contributed to adoption failure, but readers should interpret the analysis with this in mind. Second, the reflections presented here are grounded in 8 years of sustained stakeholder engagement rather than in formal qualitative data collection with recorded interviews, systematic coding, and member checking. This gives us considerable ecological breadth and depth of immersion, but lacks the methodological safeguards of structured qualitative research, and the insights may be subject to recall bias and selective interpretation. Third, all implementation attempts occurred within the Belgian health care system, with its specific configuration of hospital governance, vendor markets, and regulatory frameworks. Although we have drawn parallels with international experiences, direct generalizability to other jurisdictions should not be assumed. Fourth, criterion validation of BNuT against patient and staff outcomes was planned but could not be completed because the sociotechnical barriers described in this paper prevented sustained implementation. The system's effectiveness, therefore, remains empirically undemonstrated, and the tool should be understood as a theoretically informed prototype rather than a validated intervention. Fifth, the contrast between the single successful site and the 7 hospital sites should be interpreted with caution: the successful organization differed structurally in governance, scale, and patient population, and the comparison cannot isolate which specific factors were sufficient or necessary for adoption. Nonetheless, we believe that systematically documenting implementation failure through a structured analytical framework serves an important function in the health informatics literature, where publication bias towards successful cases limits collective learning.

Lessons Learned

The synthesis of our findings, summarized in Figure 2, yields actionable lessons for the diverse stakeholders involved in digital nursing innovation. While grounded in the BNuT experience, these insights reflect broader structural issues relevant to sociotechnical implementation in health care.

Researchers

For researchers developing digital decision-support tools, the BNuT case offers a sobering lesson. BNuT was developed bottom-up from explicit practitioner demand: nursing leaders requested better decision-support tools, and 18 health care organizations collectively crowdfunded its development. The project incorporated end user co-design throughout, with nursing managers and CNOs involved in iterative development cycles. Implementation science principles guided the approach, including stakeholder mapping, staged rollout, and continuous evaluation. Yet despite these methodological strengths, BNuT still encountered fundamental barriers that prevented adoption in most sites. This suggests that the obstacles to data-driven decision support in nursing may be more systemic than methodological: even well-designed, practitioner-endorsed innovations may fail when organizational structures do not grant

XSL•FO
RenderX

nursing leadership the authority to implement them. Researchers should therefore embed evaluation within a sociotechnical framework from the outset, document contextual mechanisms rather than merely outputs, and advocate for the structural conditions that enable adoption, not only develop technically sound tools.

Health Care Organizations

For health care organizations, our analysis underlines that the success of nursing informatics projects depends on granting nursing leadership formal authority over budget and data infrastructure. CNO enthusiasm alone cannot compensate for siloed governance or outsourced IT functions where access to the health care organization's own data is locked by software vendors. Health care organizations need to address this issue in future contract negotiations with the software vendor so that access to their proper data can be faster, more flexible, and at a much lower additional cost. Organizations that positioned nursing as an equal partner in strategic planning achieved smoother integration and sustained use. Embedding nursing analytics tools such as BNuT within long-term workforce strategies, rather than treating them as stand-alone one-fits-all pilots, fosters alignment across organizational hierarchies and improves accountability.

Policymakers

For policymakers, the BNuT experience highlights that the barriers to digital nursing innovation are systemic rather than local. Fragmented data architectures, vendor lock-in, and inconsistent interpretations of data-protection regulation create environments where interoperability remains prohibitively expensive. Concretely, this requires policy action on multiple fronts. First, mandatory interoperability standards for health IT vendors would reduce the per-project negotiation costs that limited BNuT's data integration. Second, dedicated pilot funding mechanisms for nurse-led digital health innovation could provide the financial continuity that free proof-of-concept approaches cannot sustain. The BNuT experience suggests that offering a tool free of charge may paradoxically reduce organizational commitment; phased funding models tied to implementation milestones might better incentivize sustained engagement. Third, governance reforms that mandate nursing representation on hospital IT steering committees and digital transformation boards would address the chronic underrepresentation of nursing leadership that proved decisive across our implementation sites. Addressing these "barriers of insufficiency" [17] requires structural investment in digital infrastructure and governance. Equally essential is embedding nursing leadership within national digital health strategies. Policies that enable nurse leaders to access and use workforce data are not merely equity measures but economically rational interventions that enhance quality, safety, and system performance.

Conclusions

The BNuT experience demonstrates that the challenge of digital transformation in nursing may lie less in technology than in achieving fit across sociotechnical domains. Sustainable innovation appears to depend on the concurrent readiness of human, organizational, and technological systems, none of which can substitute for another. When fit is achieved, as in the nurse-led organization, digital tools can become enablers of strategic decision-making rather than isolated projects. The persistent barriers encountered across most sites reflect structural issues that extend far beyond any single system: the undervaluation of nursing leadership, fragmented data infrastructures, and chronic underinvestment in interoperability. Equally, our experience suggests that decision-support systems of this scope must be designed with explicit attention to the data-governance capacity of target organizations, adopting modular architectures that lower the threshold for initial adoption. Addressing these systemic imbalances—in interoperability governance, nursing leadership authority, and the design of implementation-ready tools—will be essential not only for future iterations of BNuT but for the broader success of nursing informatics as a driver of resilient and learning health care organizations.

Acknowledgments

The authors gratefully acknowledge the 18 health care institutions that collectively crowdfunded the BNuT initiative and the members of the Icuro steering committee for their sustained engagement and strategic guidance throughout the project. Sincere thanks are extended to the development partners at Dashdot and Basil for their technical collaboration.

Funding

SV received a PhD grant from the Special Research Fund (Bijzonder Onderzoeksfonds, BOF) of the University of Antwerp.

Authors' Contributions

SV contributed to conceptualization, project administration, visualization, writing of the original draft, and review and editing of the manuscript. PVB and FH contributed to conceptualization, supervision, validation, and review and editing of the manuscript. WDK contributed to the review and editing of the manuscript. The authors used a large language model (Anthropic Claude) to assist in the writing process, but remain fully responsible for the content.

Abstract

Wound care is an increasing global challenge, with older adults among those most affected. As populations age, the demand for effective and efficient wound care increases. Over the years, various wound assessment and care techniques have been developed, including digital wound care technology (DWCT), which uses innovative artificial intelligence (AI). Many older adults, especially those living in rural and remote areas, face significant barriers in obtaining timely and effective wound care, leading to poorer health outcomes and increased health care costs related to wound care. These challenges underscore the urgent need to implement wound care models that equitably improve access to care and enhance clinical outcomes, particularly for older adults, to promote healthy aging and age-in-place. Based on evidence from the literature and the initial implementation of a DWCT in 2 community health systems in Ontario, this viewpoint paper encourages clinicians and health care leaders to embrace and expand the implementation of an AI-driven DWCT to address inequities in access to high-quality, timely care. The experiences from these implementations indicate that the use of AI can support clinical decision-making and extend access to care for individuals in rural and remote communities in Canada. By leveraging DWCT powered by AI, health care providers can enhance the accuracy and consistency of wound assessments, improve communication, streamline care processes, and more effectively allocate resources, ultimately aiming to reduce disparities in wound care outcomes.

KEYWORDS

wound care; AI; equity; artificial intelligence

Introduction

Wound care represents a growing challenge worldwide, particularly impacting older adults [1]. As populations age, the demand for effective and efficient wound care increases, driven by the growing number of older adults with multiple chronic conditions that predispose them to complex wounds and longer healing times. Many older adults, especially those living in rural and remote areas, face significant barriers in obtaining timely and effective wound care, leading to poorer health outcomes and increased health care costs [2]. These challenges underscore the urgent need to implement wound care models, which equitably improve access to care and enhance clinical outcomes. Traditionally, wound assessment is conducted visually to evaluate anatomical, physiological, and mechanical domains [3] or with subjective methods such as the Pressure Ulcer scale for Healing (PUSH) and Pressure Sore Status Tool (PAST) scales; these methods are widely used, can lack accuracy and consistency, leading to variable wound evaluation reports when administered by different clinicians [4].

XSL•FO
RenderX

With advances in science and technology, a range of instruments has been developed to address the growing demand for wound care. Among these, noninvasive imaging techniques have received particular attention for their potential to support wound assessment and monitoring. A systematic review of 20 studies done in 2015 summarized available approaches, including 2D stereophotogrammetry and 3D imaging methods. The authors concluded that 2D imaging is a practical wound measurement technique, offering ease of use and reliable assessments of wound size and healing progress; however, they noted that its inability to capture wound depth limits its value for care planning [5]. Building on this, a 2022 scoping review of 156 global studies examined the development, evaluation, and implementation of digital health technologies (eg, imaging and measurement) for wound care [6]. This review highlighted growing adoption of digital tools, citing evidence of their acceptability, feasibility, effectiveness, and clinical impact. At the same time, it identified important challenges, including limited evidence in hard-to-reach populations (eg, those in remote regions), low uptake linked to noninclusive design processes, and uncertainty around cost-effectiveness. It is essential to note that this review was not specifically tailored to older adults, a population at elevated risk of wound development and delayed healing due to comorbid conditions, and who also experience disproportionate barriers to care arising from age-related, geographic, and socioeconomic factors.

This study is a forward-looking perspective that highlights the current context of wound care in Canada and explores the potential for artificial intelligence (AI) driven digital wound care technology (DWCT) to improve access, efficiency, and equity. The authorship of this study reflects the multiple perspectives shaping this work, including 2 community health systems implementing a DWCT, the evaluation team supporting that implementation, academic and government partners advancing digital health innovation, and representatives from the company developing the technology. By bringing together these complementary experiences, we aim to provide a salient commentary on the merits of AI-augmented DWCT and its potential to advance equity, access, and efficiency in wound care in Canada.

The initial implementation of a DWCT in 2 rural and/or remote community health care systems, presented here as case studies, illustrates the contextual challenges faced by health care providers and patients while also offering practical insights into the technology's application and benefits. Discussion of anticipated challenges in implementing AI technologies in wound care provides a roadmap for future research directions, including identification of potential facilitators and barriers to adoption and uptake of the DWCT in the 2 networked community health systems. The potential for AI in transforming health care delivery is vast, particularly in the field of wound care, and can play an important role in ensuring that all patients receive high-quality, equitable care across diverse geographies.

Wound Care in Canada

The Canadian population is experiencing a significant demographic shift, with older adults (65 years and older) rapidly becoming the fastest-growing demographic, and by 2051, they could represent 25% of the population [7]. Aging is associated with the accumulation of cellular and molecular damage within the body, which can manifest as frailty and/or chronic health conditions [8], which increases vulnerability to complex wounds, meaning the number of older adults needing wound care is anticipated to increase substantially in the future [9]. Although the exact prevalence of wounds requiring care in Canada is unclear, estimates suggest that up to CAD $11.1 billion (US $8.18 billion) are spent annually on wound care [9]. Approximately 1 in 500 Canadians develops nonhealing wounds [10], which significantly impacts the health care system [11]. In Ontario alone, 30% - 50% of health care delivery involves patients with wounds, predominantly affecting older adults who often heal at home [11].

In 2019, older adults constituted 17% of Canada's population but accounted for 47% of total health care costs [10]. Rural and remote areas of Canada are aging more rapidly than their urban counterparts [12]; yet, they often have fewer health resources, especially health human resources (HHR) [2]. This lack of access to timely treatment for complex wounds leads to improper treatment of up to 25% of Canadian patients [13]. Chronic wounds impose significant physical and emotional burdens, decreasing patients' quality of life and increasing health care costs [14,15]. Without regular, high-quality care, these wounds can lead to serious complications such as infections, hospitalization, amputation, and even death [1].

The complexity of wound care is exacerbated by limited opportunities for comprehensive wound care education for health care providers, who typically receive fewer than 10 hours of formal instruction [16]. During training, health care providers are taught to provide quality care and maintain optimal functioning, including the treatment of health conditions such as wounds, through supportive, preventive, therapeutic, palliative, and rehabilitative care. However, these professionals need additional training to fulfill the specific needs of care and their respective professional scope of practice. For example, the College of Ontario of Nurses specified the scope of practice for registered nurses (RNs), registered practical nurses (RPNs), and nurse practitioners (NPs), which includes 5 regulated acts, including performing a prescribed procedure below the dermis or a mucous membrane [17]. While this authorized act consists of wound assessment and wound care, which are at the entry level, nurses with advanced education, such as NPs, have an extended scope of practice and are authorized to diagnose, prescribe medications, and other treatments for clients [17]. Similarly, British Columbia has specified the pacified authorities at entry level and advanced level, which is presented in the Wound Care Canada by Freeman et al [18]. In addition, the British Columbia Provincial Nursing Skin & Wound Committee, in collaboration with the wound care clinicians from across all health authorities, has devised the wound assessment and treatment flow sheet: documentation guide (version 2, 2018) that specifies nurses' roles with regard to wound assessment and documentation for varying types of wounds [19].

Traditional methods for tracking wound healing progress, such as using a paper ruler and cotton swab for wound assessment, result in high clinical variability and a 44% error rate in infection

XSL•FO
RenderX

identification [20]. Furthermore, health care education and wound care tools have traditionally been developed with lighter skin tones in mind, leading to inaccurate assessment for patients with darker skin [21]. Additionally, rural communities in Canada are diverse, not only in terms of geographic characteristics such as population size, density, or distance from urban centers, but also in social aspects, including social representation and resource availability [18,22,23]. There is growing concern regarding the shortage of health care providers in remote and rural regions, further intensifying the issue of care access for older adults. The Canadian Institute for Health Information reports on the declining trends of health professionals in rural or remote areas, including for nurses, NPs, and pharmacists over a decade, and stagnant growth for rural family physicians [2]. Reducing health disparities, particularly in rural and remote areas with finite resources, requires innovative solutions, including consultation models and enhanced access to best practice care [24]. These dual drivers, population aging and uneven resource distribution, underscore the urgent need for effective health care solutions that:

1. Enable individuals to age in place while living with aging-related health conditions, including chronic and complex wounds.
2. Support the provision of best-practice clinical care in areas where specialized health care human resources are limited.
3. Reduce the challenges associated with human error and biases.

To meet these needs, innovative technologies such as AI offer promising solutions that can enhance efficiency, access, and quality in health care delivery.

AI-Enhanced Wound Care as a Solution

AI has the potential to transform medical practices and service delivery in health care, including enhancing productivity, improving patients' flow, experience, care, and quality of life [25] and enhancing providers' experiences and safety [25,26]. The positive impacts of AI in clinical care include enhanced accuracy in diagnostics, improved patient engagement, and increased treatment support [25]. AI has been leveraged in wound care, providing more efficient and effective solutions for acute and chronic wounds [27]. AI-driven algorithms have proven effective in measuring wound dimensions and identifying prognostic features, such as tissue composition, granulation, slough, eschar, and exudate. These elements are crucial for assessing wound burden and predicting the healing trajectory [28].

Our Implementation Experience: Project and Team

To illustrate how AI-augmented wound care can enhance equity, access, and efficiency, we draw on our collective experiences implementing a DWCT in 2 networked Canadian community health systems. The following section describes the technology itself, the project sites, and the multidisciplinary team involved in its adoption, highlighting both practical considerations and lessons learned in real-world settings.

The Digital Wound Care Technology

The DWCT under implementation, Swift Skin and Wound (Swift), is developed by Swift Medical Inc. and is deployed in more than 5200 health care facilities internationally, spanning the continuum of care. Swift Skin and Wound is a software-based, noninvasive digital wound assessment application installed on smart devices. The software captures clear imaging enhanced by HealX (Swift Medical Inc), a Health Canada and US Food and Drug Administration–registered fiducial marker for real-time calibration of wound images on smart devices, using AI-driven algorithms that auto-trace wound edges, precisely measure wound surface area, and facilitate comprehensive documentation [29]. These features offer advanced analytical and tracking insights to clinicians, empowering them with data-driven assessments to support wound care management [28,29]. This DWCT also enhances communication among the interdisciplinary care team through the centralized dashboard portal, which provides a comprehensive, real-time view to support coordinated care management. The dashboard enables the care team to review patient information, track progress, and provide recommendations, facilitating coordination of care.

Recently, Swift Skin and Wound added additional features: AutoDepth, SmartTissue, and HealingIndex. AutoDepth automatically calculates the visible depth of wounds, measures the wound, and accurately identifies and records its deepest point on a smart device. SmartTissue detects and quantifies tissue types including epithelial, granulation, slough, and eschar within the wound bed, irrespective of skin tone, using deep learning and vision architectures designed to run locally on a wide range of smart devices [30]. HealingIndex uses deep learning and machine learning algorithms to analyze a range of wound characteristics, including wound size, tissue composition, wound type, location, and wound exudates' type and amount to predict healing trajectories of wounds [28]. By using these sophisticated AI-driven algorithms, providers can achieve rapid and precise assessments of wounds and their characteristics and use predictive modeling to project healing trajectories and inform clinical decision-making for care plans (Figure 1).

XSL•FO
RenderX

Figure 1. A sample wound on the ankle area, showing a clinical presentation where objective and consistent wound assessment, supported by an artificial intelligence–driven tool for measurement and tissue classification, can enhance effective monitoring, especially in settings with limited access to specialized expertise.

Evidence from implementations, mostly in US health systems, indicates that integrating Swift's DWCT into wound care programs can improve clinical outcomes [31,32], enhance operational efficiency [29,32], reduce costs [31-33], and increase clinician satisfaction [34].

While other digital wound care technologies exist, this viewpoint focuses on Swift's DWCT because the authorship team is uniquely positioned as active implementation partners in Canadian health systems. We draw on the published literature to provide context and evidence, but we triangulate these insights with our direct, real-world experience to highlight equity, access, and efficiency considerations that emerge in practice, providing insights that would be difficult to capture from literature alone.

Project Description

This project uses an implementation research approach to evaluate the adoption of the DWCT in 2 networked Canadian health systems, aiming to identify facilitators, barriers, and lessons for broader AI-driven wound care implementation.

Implementation Site 1: Giishkaandago'Ikwe Health Services

Giishkaandago'Ikwe Health Services (formerly Fort Frances Tribal Area Health Services) is an Indigenous-led health organization in Northwestern Ontario. The accredited organization provides holistic health services to the 10 Anishinaabe Communities of Southern Treaty 3. The Home and Community Care Program offers essential services in the home and community setting, including advanced wound care through a nurse-led DWCT tool.

Giishkaandago'Ikwe initiated implementation of the DWCT in February 2022 as a quality improvement initiative. This site has particular expertise in leveraging technology to provide care across remote geographic regions. Given the high amputation rates in the region, the home and community care team implemented the DWCT to strengthen decision-making for wound management through efficient documentation and communication, with the goal of enhancing healing rates and reducing amputations.

The interdisciplinary wound care team includes RNs, RPNs, including 2 Skin Wellness associate nurse (SWAN)–trained RPNs, personal support workers (PSWs), and a physiotherapist with advanced wound care training (Masters of Clinical Science in wound healing). In total, the team includes 14 wound care clinicians, supported by a wound care champion and a home and community care coordinator. Foot care nurses conduct wound assessments and communicate findings to the home care team, while other community health nurses contribute through public health programming and wound care support.

Team members complete an 8-hour online wound care training upon hire if they do not already have advanced wound care education. In addition, the team participates in an annual, full-day, hands-on internal wound care workshop to reinforce clinical skills. Weekly SWIFT rounds provide structured opportunities for case review, collaborative problem-solving, and ongoing knowledge exchange.

Implementation of the DWCT was completed over 1 month, supported by training and mentorship from both SWIFT and the site's internal champion (the home and community care coordinator). Initial training consisted of a 1-hour virtual session, followed by ongoing support throughout the implementation period. Due to the team's small size, strong collaboration, and

XSL•FO
RenderX

existing wound care expertise, adoption of the technology was rapid and well integrated into practice. The AutoDepth feature has been actively used in patient care, and team members completed SmartTissue training in January 2025.

Implementation Site 2: Brightshores Health System (Brightshores)

Brightshores Health System is a comprehensive health care network serving the rural Gray and Bruce counties in Ontario, Canada. It operates 6 hospitals (Owen Sound, Meaford, Markdale, Southampton, Wiarton, and Lion's Head), each with 24/7 emergency departments. Brightshores services encompass medical and surgical services, including complex surgeries, total joint replacements, cancer treatments, advanced diagnostic imaging such as magnetic resonance imaging and computed tomography scans, and wound care. Across the system, over 400,000 visits per year are reported, and approximately 2200 staff members with over 250 dedicated physicians deliver patient care across the region, including wound care.

Implementation of the DWCT began in 2024, initially within the regional diabetic foot ulcer clinic. Within months, 35 clinical staff were trained as technology champions, and by October 2024, the DWCT was rolled out to multiple departments across all 6 hospitals. Initial training was performed in-person (2.5 h) with an asynchronous online portion (1.5 h) facilitated by the research team and a nurse specialized in wound, ostomy, and continence (NSWOC), with a focus on use of the AI technology, clinical data entry education, and workflow processes. Users included RNs, RPNs, clinical coordinators, NPs, nurse clinicians, and PSWs. Within 6 months, it was noted that the turnover of staff necessitated continuous training opportunities. An online training module has been developed specifically for the Brightshores sites, which will be more accessible and enable quicker onboarding for staff across multiple sites. Deployment of SmartTissue began in December 2024 and continues across sites.

Discussion

AI-Powered Digital Wound Care Could Improve Access, Enhance Efficiency, and Address Inequities

Overview

Wound care is a critical component of comprehensive home health services. The prevalence of older adults as recipients of home care is notable, with a substantial proportion necessitating wound care due to conditions such as pressure injuries, postsurgical recovery, and complications arising from venous ulcers. Older adults prefer to receive wound care in community settings [35], citing pain, transportation barriers, and risk of exposure to infection in the clinic as primary drivers of preference [36]. Patients and family caregivers frequently report feeling inadequately prepared to participate effectively and confidently in wound care [37]. The presence of nonhealing wounds and associated complications can profoundly affect quality of life, increasing risk of infections and hospitalization [38].

Access

In the Canadian context, the potential for an AI-enhanced DWCT to increase access to best practice care is particularly significant. The "Caring for Canadians" study highlights a significant gap between the supply and demand for HHR in Canada, a gap that is already evident and expected to widen over the next decade, with rural and remote communities feeling the impacts most acutely [39]. Specialist HHR, such as NSWOCs or additional training in wound care, is in high demand. However, recruiting and retaining specialized health care workers is challenging, which has led to the adoption of innovative, technology-enhanced care models to optimize resource use [2,24].

In Canada, geographic location is a primary factor determining access to care, with isolated and remote communities experiencing the highest levels of deprivation [40]. These communities are frequently located in northern regions of the provinces and territories and are often home to Indigenous groups [40]. First Nations, Métis, and Inuit people, along with those of African, Caribbean, Southeast Asian, and Latin descent, have higher prevalence and incidence of diabetes and higher rates of lower extremity amputation because of diabetic foot ulcers and peripheral arterial disease [41]. This is particularly evident in Indigenous populations, where the rate of major amputations due to diabetic wounds is up to 49 times higher than in non-Indigenous populations [42]. This may be attributable to poor access to health care, barriers to clear communication, cultural differences, and discrimination [43]. Within this context, the AI-augmented DWCT offers an opportunity to increase access to best practice care by leveraging available resources and supporting available staff to work at the frontiers of their scope of practice (Textbox 1).

XSL•FO
RenderX

Textbox 1. Case study: Giishkaandago'Ikwe Health Services.

The team at Giishkaandago'Ikwe Health Services uses digital wound care technology (DWCT) for all aspects of wound assessments. Leveraging this technology has strengthened communication internally and externally with care partners. Enhanced communication is central to improved outcomes, illustrated here through a client story.

A client was referred by the Emergency Department after seeking care for painful, reddened foot wounds that had worsened following several weeks of self-treatment. The team initiated a comprehensive wound assessment completed by a personal support worker (PSW) using the SWIFT app. PSWs are unregulated care providers who assist individuals with activities of daily living (ADLs) and instrumental activities of daily living (IADLs).

A holistic treatment plan was then created by the interdisciplinary team during SWIFT rounds. Giishkaandago'Ikwe Health Services mobilized available staff to provide care, ensuring they were supported to work to their full scope of practice. The client observed weekly progress through the app, which increased their engagement and adherence to the care plan. The team also used dashboard-generated reports to share wound progress with external health care providers.

Through this collaboration, the client's care was escalated appropriately, enabling timely access to vascular surgery and chiropody for specialized offloading. The client received these services in a tertiary center and was able to return home promptly, with the Giishkaandago'Ikwe team providing ongoing follow-up.

Despite a late start to wound care and the need for surgical intervention, the client's wounds fully healed within 5 months—an excellent outcome for a case at high risk of amputation. Importantly, the majority of the client's care occurred within their home community, minimizing disruption to their family and caregiving responsibilities. The ability to coordinate and communicate effectively across providers using DWCT was key to avoiding prolonged hospitalization and ensuring continuity of care close to home.

In the Giishkaandago'Ikwe Health Services case study, the DWCT enabled a PSW who had direct contact with the patient to complete a wound care assessment even though this typically would be conducted by nursing staff. The DWCT tool enabled the team member who was geographically co-located to effectively capture the data needed for the wound care team to create a full care plan, without requiring the patient or the specialist providers to travel. In such scenarios, AI-augmented DWCT can support an available staff member to work at the frontiers of the scope of practice while maintaining direct connections for clinical escalation and consultation when needed.

This is particularly relevant in the Canadian rural and remote context, where geography and inclement weather can act as a barrier to access. A 2020 review of barriers to equitable access identified the lack of year-round roads, extreme winter weather events, and the absence of rural and remote hospital staffing as key contributors to poor access to care in Indigenous communities [44]. That same review identified telehealth and telehealth-enabled consultation models as a mitigator of inequitable access. Furthermore, the review noted that telehealth enables community health workers and nurses to provide additional services in their local community and reduces the burden on patients to travel long distances to access care. This has important implications for equitable access, as community care providers typically have higher levels of trust and greater ability to provide culturally safe care [45].

The DWCT augments traditional "telehealth" in wound care by adding empirical data in the form of high-quality, time-lapsed photos in a "dashboard" that can be accessed by patients, caregivers, and the entire wound care team. This enables tracking of wound trajectory and gives contextual clinical data to geographically remote specialist providers such as NSWOCS, endocrinologists, and vascular surgeons. Additionally, the dashboard supports team communication as it offers a shared point of reference to facilitate collaborative care planning. In the context of an optimized scope of practice, this feature provides an additional layer of protection—ensuring specialized clinical oversight of geographically remote patients being cared for by practitioners working at the frontier of scope of practice. Furthermore, this supports staff who may not have clinical training in wound care by providing avenues for consultation and escalation to complement their clinical judgment. Ultimately, this benefits patients who receive care from a trusted provider in their community, while retaining the benefit of review and consultation from clinical experts.

The AI-augmented features of the DWCT expand access to best practice care by (1) enabling patients in remote communities to access services without necessitating travel, (2) empowering clinicians practicing in rural and remote communities to work with an optimized scope of practice, and (3) supporting communication and ensuring all members of the care team have access to relevant clinical information.

Efficiency

Optimization of clinical resources is required to ensure efficiency and maximize the number of patients who receive best practice care. The AI-enhanced DWCT tool can increase clinical efficiency by conducting rapid assessment of wounds and streamlining consultations and escalations [28]. A key component of effective wound care is assessment of wound size. Traditionally, this is done with paper rulers, and the wound size is calculated using a formula that multiplies length by width. However, this traditional method is ill-suited to irregularly shaped wounds, leading to overestimation of size in 36% - 74% of nonrectangular wounds [46-48]. Patients with darker skin tones, wounds characterized by diffuse edges, irregular shapes, necrotic tissue, or unhealthy surrounding tissue are more prone to having their wounds overestimated in size [46]. A more accurate calculation of wound size can be captured using a tracing method, where transparency film is placed over the wound and outlined, but this is reported to be time-consuming [49]. Accurate and objective measurement of wounds is essential as a change in wound size is a key predictor of wound healing trajectory [5]. Digital wound measurements powered by AI are emerging as a more efficient and accurate means to measure wounds [46,50-52] (Textbox 2).

XSL•FO
RenderX

Textbox 2. Case Study: Brightshores Health System.

Brightshores Health System is spread throughout 8600 square kilometers in Southwestern Ontario. Residents are among the oldest average age in the province, with the fastest-growing segment of the population aged between 65 and 84 years. The region has a significant population of patients with chronic disease and wounds, but Brightshores is limited to 1.4 Nurses Specialized in Wound, Ostomy, and Continence (NSWOC's) for the 6 hospital sites.

This means that daily, multiple wounds can present at any one of Brightshores hospitals, and the reality of limited resources means limited and delayed response time. Furthermore, without access to specialists and with limited tools, frontline nursing staff struggle to accurately assess wounds. The DWCT has presented an opportunity for frontline staff to take photos of wounds, allowing for accurate and detailed assessments that can be digitally accessed by the NSWOC and all providers within the circle of care. Providing frontline staff at all 6 hospital sites with a tool to accurately assess wounds allowed for a reduction in reliance upon the NSWOC.

Within the first year, over 1000 km of NSWOC travel time has been saved, allowing them to devote more time to direct patient care. Since the implementation of this DWCT, initial trends show a promising decline in amputation rates and fewer visits of outpatient wound care patients attending the emergency departments due to wound complications, compared to the previous year. Patients are reporting that their assessments performed with the DWCT are more comfortable than traditional methods and are reporting that the use of DWCT has improved their wound care experience.

In one patient's story, the patient felt discouraged about the lack of visual improvement they were able to detect with their eyes. With the use of the DWCT and historical measurements, the patient was able to monitor progressive wound closure, aligning with compliance to treatment recommendations, and was happy to experience a full wound closure within a month of using Swift.

Brightshores' continued hope is that the use of this technology will empower nurses to gain confidence and become more involved in wound assessments, enabling prioritization of wound care, and that this technology will enable patients to see progression in healing over time.

This case study highlights the benefits of tools that enable the clinical care team to optimize their time and streamline processes for escalating concerns to specialized care resources. Use of the DWCT is faster and clinically equivalent in accuracy compared to manual methods of wound measurement and capture [29,53]. Enhanced DWCT reduces the overall time required for wound measurement and documentation and has been shown to result in an average time saving of 1.01 - 2.39 minutes per wound assessment when compared to the traditional manual methods [29]. Given the known constraints on clinicians' time, burden of documentation, and anticipated workforce shortages, these time savings represent an opportunity to increase both efficiency and access.

AI tools can also help identify and escalate wounds that require review. HealingIndex is a new feature of the DWCT that uses machine learning algorithms to assess the photographs of the wounds that are submitted by clinicians. This tool analyzes the photo to identify wound characteristics associated with healing including wound size, tissue composition, and exudates, to predict the healing trajectories of the wound. The HealingIndex AI Model uses deep learning techniques to examine patient wound records, images, and characteristics, producing a score from the AI model that indicates the level of risk for delayed healing and potential deterioration [28].

While traditional care pathways rely on clinicians identifying and escalating wounds that are deteriorating or at risk of deteriorating, the HealingIndex automates these processes using a predictive algorithm. This allows the wound care team to rapidly identify and prioritize wounds that require specialist input. This identification reduces the risk of deterioration and complications that necessitate hospitalization or amputation, reducing overall health care costs associated with wound complications [1,31,38]. Furthermore, the use of this AI tool can identify wounds at risk for slow healing, which may require an adapted wound management protocol. By reducing complications and adapting the treatment of slow-healing wounds, the AI tool can reduce the overall costs associated with wound care [31]. Early identification of wound deterioration is crucial as it allows timely intervention, preventing progression and potentially leading to significant savings for the health care system through avoidance of unnecessary costs [34].

The use of the predictive algorithm may also augment clinical decision-making by identifying wounds that are healing effectively and therefore may not need daily or thrice-weekly dressing changes. Reducing the frequency of dressing changes reduces supply costs and frees patient and provider time. Reducing the frequency of dressing changes to once a week, where clinically appropriate, can free up thousands of hours of nursing time over the course of a year [54]. Overall, the AI-powered DWCT can enhance clinical efficiency by automating escalation and review processes.

Additionally, the DWCT platform provides opportunities for asynchronous collaboration. Specialists are able to review patient records, including high-resolution time-lapse photos, and provide recommendations without requiring geographic co-location or congruent timing. This enables the specialist wound care nursing team to optimize their time by reducing travel between sites, reducing administrative burden, and creating care plans that can be executed by staff located near the patient. This offers the benefits of not only efficiency but also equity, as access to best practice care and consultation is no longer limited to the fortunate few who can be reviewed by the specialist nurses in person. In rural and remote parts of Canada, which, as noted above, are struggling to recruit and retain skilled providers, these tools enable more patients to access specialist consultation and review without necessitating travel.

AI-powered DWCT can support increased efficiency by (1) reducing time spent on manual assessment and measurement of wounds; (2) automating escalation by flagging deteriorating wounds for review, which enables prioritization of at-risk patients for intervention; and (3) enabling collaboration between frontline staff and specialist wound care resources without requiring geographic colocation or time alignment.

XSL•FO
RenderX

Equity

Universality and accessibility are embedded within Canada's Health Act, and equity must be centered as a priority. Inequities in the Canadian health system exist, especially related to disparities in health outcomes for rural and remote populations, and disproportionately affect First Nations, Inuit, and Métis communities who face burdens associated with travel and costs [44]. Rural health care policies are often guided by urban care models, which can exacerbate these inequities for rural communities [24].

Many rural, remote, and Indigenous communities experience inequitable access and poor outcomes, which may be attributable in part to resource shortages. Additionally, human biases, racism, colonial legacies, and historically unbalanced relationships between service users and providers also play a key role. Nyugen et al [44] explicitly state "Colonization and historical intergenerational traumas... have plagued the survivors and later generations with physical and mental trauma," and "...many Health Care providers do not acknowledge the impact of colonization on the Indigenous community and disregard the social determinants of health as explanations for illness." This, in turn, manifests as culturally inappropriate health services, which deter people from seeking health care.

In this context, the AI-enhanced DWCT can support more equitable care by enabling community care providers with existing, trusting relationships to provide culturally safe care. This approach is aligned with mitigation strategies proposed by Indigenous health experts who highlight the importance of community partnerships and provision of culturally safe care [44,45].

Furthermore, patients with darker skin tones disproportionately experience poor wound outcomes, which may be attributable to both inequities in social determinants of health and limitations in provider ability to accurately identify clinically relevant changes in tissue in pigmented skin [55]. Johnson et al [55] note that erythema is an excellent example, as its presentation varies based on skin tone, and historically, medical education has failed to account for diverse skin tones in training and published literature [21]. Darker skin tone is associated with overestimation of wound size when using standard "width X length" measurements [46]. In comparison, the DWCT with AI-augmented AutoTrace, AutoDepth, and SmartTissue is able to provide accurate measurements and can enable color calibration to adjust for light conditions and skin pigmentation [46]. Thus, the use of the AI-enhanced DWTC can support more accurate measurements and potentially overcome some of the implicit biases that health care providers manifest.

Next Steps

While AI-enhanced tools offer immense promise to support better care efficiency and outcomes, there are several key considerations that must be addressed to ensure equitable and trustworthy implementation. One of the pressing concerns is the representation of diverse patient populations in AI systems. When datasets fail to capture diversity across factors such as skin tone, age, and other demographic variables, resulting models can produce biased or inaccurate outputs. These biases are particularly problematic in clinical contexts like wound care, where diagnostic accuracy is critical. Diverse groups, such as individuals with darker skin tones or older adults, are often underrepresented in training datasets, leading to biases in AI outcomes. This underrepresentation can result in inaccurate diagnoses or recommendations, which are harmful and counter to the goals of quality wound care. Human biases embedded in AI systems can become enshrined or even amplified if not intentionally designed with equity in mind [25]. Such biases arise when AI models are trained on datasets that do not adequately represent the diversity of the population, including those most likely to experience wounds, such as older adults [56]. Chu et al [56] emphasize the known challenges of ageism in AI, noting that models often overlook older adults due to insufficient data representation. To counteract these biases, it is essential to increase the diversity of AI training datasets and maintain robust evaluation protocols that ensure accuracy and interrater reliability across patient populations. These safeguards are crucial in mitigating the risks of bias and ensuring that AI systems are fair and inclusive.

In addition to addressing bias, overcoming skepticism and implementation barriers is crucial for the successful adoption of AI-enhanced technologies, particularly among older adults. While the stereotype of older adults as technophobic is increasingly being disproven [57], structural barriers such as the cost of technology and access to reliable internet remain significant hurdles for many older adults in rural and remote communities [58]. Despite these challenges, patients are generally open to the use of AI in health care if appropriate regulatory and safety oversights are in place [59]. Pilot studies, such as those by Wang et al [52] and Raismam et al [60], show promising results regarding patient acceptance of AI for wound care [52,60] while Mohammed et al [34] highlight positive provider acceptance [34]. These studies indicate a growing receptiveness toward an AI-augmented DWCT, but continued exploration into unique barriers, especially those pertinent to the Canadian context, is necessary.

The evaluation being conducted by this team will enhance understanding of implementing AI-enhanced DWCT in rural and remote communities in Canada. This evaluation will identify specific barriers and facilitators of adoption, ultimately leading to the creation of a framework that supports wider adoption and integration of technologies to support healthy aging. By addressing these issues, the path toward equitable, efficient, and widespread use of AI technologies in health care becomes clearer, fostering a more inclusive technological future.

Abstract

Background: Digital technologies are increasingly being introduced into the health care system and in settings such as hospitals and geriatric long-term care (LTC) facilities, offering potential benefits such as improved care quality, reduced workload, or enhanced documentation processes. However, the success of these technologies also depends on the acceptance by the primary users, that is, the nursing staff.

Objective: This review synthesizes empirical studies that have explored the acceptance of digital technologies by nursing staff in geriatric LTC settings, building upon the foundational work by Yu et al (2009). The goal is to identify influencing factors, assess the extent of existing evidence, and highlight research gaps in this care setting.

Methods: A systematic literature review was conducted following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines. The SPIDER (sample, phenomenon of interest, design, evaluation, research type) framework was used for eligibility criteria. Databases searched included PubMed, ACM Digital Library, Web of Science, and the Health Administration Database ProQuest. Studies were included if they empirically examined the acceptance of digital technologies by nursing staff in geriatric LTC settings. Two reviewers independently screened the studies, extracted data, and assessed methodological quality using the CASP (Critical Appraisal Skills Programme) checklist.

Results: A total of 3 studies met the criteria, highlighting a gap in research on this topic. The studies applied cross-sectional quantitative designs and highlighted critical determinants of technology acceptance, including perceived usefulness, ease of use, digital competence, and organizational support. The studies involved a total of 1019 participants from Germany, Australia, and the Netherlands. Barriers included lack of user involvement, lack of training, poor system design, and demographic differences in digital affinity.

Conclusions: This review shows that the acceptance of digital technologies by nursing staff in geriatric LTC settings is shaped by a constellation of individual factors, such as digital competence and perceived relevance of technology, as well as organizational factors such as access to training and involvement of staff in the implementation process. Despite these insights, the limited number of empirical studies highlights a research gap in this care setting. To ensure sustainable digital transformation in geriatric LTC, future research should prioritize rigorous and participatory approaches, using longitudinal, intervention-based, or multilevel study designs.

Introduction

Overview

"A promising approach to understanding social dynamics lies in conceiving our society as a globalized knowledge society undergoing a comprehensive and multifaceted digital transformation" [1]. The adoption of digital technologies in health care and nursing care reflects the complex digital transformation taking place across society [2]. Digital technologies are already having an immense impact on how nursing care is delivered [3-10]. In elderly care settings, particularly in geriatric long-term care (LTC) facilities, digital technologies such as electronic health records, assistive robotic systems, telehealth apps, assistive sensory systems, information

XSL•FO
RenderX

and communication technologies, or artificial intelligence monitoring platforms [4,9,11] offer important opportunities to address current and future challenges [12-15]. These include workforce shortages, improving working conditions, or increasing the attractiveness of the nursing profession. The demographic shift associated with an aging population [16] is also one of the major challenges in this context. In Germany, the number of individuals in need of LTC rose to over 5.7 million people by December 2023 [17], with projections indicating a further increase in this number. In Germany, several programs were initiated for supporting the digital pathway [18,19]. The Bavarian State Chancellery decided in a cabinet meeting on March 19, 2024, to promote digitalization in health care and nursing. The goal is to further improve medical and nursing care for the population [20]. On the other hand, not only is the demand for LTC places increasing, but also the need for nursing staff in general is growing [21].

The real-world implementation of digital innovations in the health care system, especially elderly care, remains inconsistent and is frequently challenging [7,22-25]. One of the most significant challenges is the level of acceptance among nursing staff [26-29]. As the primary users of these technologies and new systems, nursing staff play a crucial role in determining whether such tools will be adopted and integrated into everyday work [15-19]. While research in acute and primary care has increasingly examined digital transformation through staff training, workflow redesign, and implementation frameworks, geriatric LTC remains comparatively underexplored. In acute care settings, digital competence programs and structured IT implementation strategies are often supported by institutional infrastructure [30,31]. Theoretical models such as the technology acceptance model (TAM) [32] or TAM2 [33] highlight that perceived usefulness and perceived ease of use are key predictors of user acceptance [34]. However, practical experience shows that digital transformation, especially in the field of care, often falters at the stage of user engagement, particularly when it fails to consider organizational, cultural, ethical, and educational conditions [2,5,10,35-38]. In geriatric LTC, where staff is more involved in basic care of older adults, these challenges become even more important [14,39-41]. A simple example of how digital technology in geriatric LTC could avoid high risks and time waste of the nursing staff is the occurrence of discrepancies between medication plans sent via fax by general practitioners and the actual administration records in nursing homes. Paper-based updates made during medical visits are sometimes not transferred into the official documentation, creating dangerous information gaps and avoidable risks for residents. This example illustrates how outdated communication practices and the lack of integrated digital infrastructures can compromise care quality and safety. It further highlights the importance of user-accepted digital solutions in daily nursing work and a scientifically grounded framework for implementation in LTC. Geriatric LTC facilities often face limited access to training resources and less technical and managerial support for digital adoption. Consequently, empirical evidence on how nursing staff in LTC acquire digital skills, engage in technology implementation, and perceive organizational support remains scarce. This gap underscores the need for research specifically focusing on acceptance factors, training needs, and contextual barriers unique to geriatric LTC, rather than extrapolating findings from hospital-based studies. Despite the critical role of nursing staff in implementing digital innovations, scientific evidence addressing their perspectives, needs, and acceptance in LTC contexts remains very low [25,42].

Objective

Despite considerable political interest and investments in digital transformation, the success of such efforts in the care setting hinges on a crucial factor that remains underexplored, at least in the geriatric LTC, which is the acceptance of digital technologies by nursing staff. Their perspective is not only relevant but essential to the sustainable implementation of digital solutions in care. The primary objective of this systematic review is to synthesize existing empirical research that investigates the acceptance of digital technologies among nursing staff in geriatric LTC settings, building upon the work of Yu et al [39], which was one of the first studies with focus on acceptance factors among nursing staff in LTC, published in 2009. By identifying the most relevant influencing factors, the review contributes to a better understanding of the conditions under which circumstances digital innovations can be effectively and successfully implemented in geriatric LTC environments, with particular attention to the acceptance factors of the nursing staff in this setting.

Methods

Study Design

This systematic review was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines (Checklist 1) [43]. For the development of the eligibility criteria, the SPIDER (sample, phenomenon of interest, design, evaluation, research type) framework [44] was applied to ensure a structured and targeted selection of studies.

Eligibility Criteria

The eligibility criteria and methodological steps were defined a priori; however, no protocol was registered for this review. The inclusion and exclusion criteria were defined in alignment with the SPIDER components (Table 1), focusing for instance on studies involving nursing personnel in LTC (sample); their acceptance of digital technologies (phenomenon of interest); and empirical research designs with quantitative, qualitative, and mixed methods approaches (design and research type). This focus reflects the review's aim to identify scientific evidence on how acceptance shapes digital adoption among LTC nursing staff. The studies had to be peer-reviewed and published in English or German. Exclusion criteria comprised studies conducted only in hospital, outpatient, or home care environments, as well as research focusing on other professional groups without separately analyzing the nursing staff perspective. Although qualitative and mixed methods studies were eligible according to the SPIDER framework, no such studies met all inclusion criteria (ie, focus on nursing staff in geriatric LTC and explicit assessment of technology acceptance). As a result, all included studies employed cross-sectional

XSL•FO
RenderX

quantitative designs. This limitation is discussed in the *Results* and *Discussion* sections, but the inclusion parameters were retained to ensure methodological consistency and comparability across studies.

Table . Inclusion and exclusion criteria—SPIDER (sample, phenomenon of interest, design, evaluation, research type) components.

SPIDER components	Inclusion criteria	Exclusion criteria
S=Sample	• Nursing staff employed in long-term care facilities (nursing homes, elderly care)	• Studies focusing in general on non-nursing staff (eg, administrators, managers) • Studies involving participants who are not working in long-term care facilities • Studies with samples not clearly defined as nursing staff in geriatric long-term care
PI =Phenomenon of interest	• Acceptance, adoption, barriers, experiences related to digital innovations in care settings, including technologies like electronic health records, telehealth services, assistive robotics, digital documentation, sensory, ICT[a], IoT[b], AI[c]-driven decision support systems	• Studies focusing only on nondigitalized operations in long-term care • Studies exclusively addressing competencies and education without looking at technology acceptance • Studies not involving digital technologies
D=Design	• Intervention studies, observational or cross-sectional surveys, studies employing qualitative, mixed methods designs	• Nonresearch
E=Evaluation	• Outcomes related to staff attitudes, perceptions, barriers, willingness to use, fears, and facilitators to adoption, satisfaction, perceived usefulness of digital technologies in long-term care	• Studies not reporting on outcomes related to staff digital technology acceptance • Studies focusing solely on managerial or administrative evaluations without staff input. • Studies focusing only on nursing staff from hospitals or private home care settings
R=Research type	• Qualitative, quantitative, or mixed methods research focusing on the care employees regarding digital innovation adoption • Peer-reviewed journal articles published between January 1, 2010, and December 31, 2024 in English or German	• Conference papers, reviews, editorials, letters to the editor, and studies not published in peer-reviewed journals • Publications not in English or German • Studies published outside the specified date range before January 1, 2010 (except for Yu et al [39])

[a]ICT: information and communication technology.

[b]IoT: internet of things.

[c]AI: artificial intelligence.

Search Strategy

The search strategy employed an inclusive keyword combination, which was discussed and refined beforehand. Boolean operators were used to capture the intersection of acceptance, digitalization, technology, nursing, and geriatric LTC. The primary search string used was as follows: (“acceptance” AND (“digital technology” OR “digital” OR “technological” OR “artificial” OR “robotic” OR “digitalization” OR “artificial intelligence” OR “IoT” OR “robot” OR “virtual reality” OR “socially assistive robots” OR “digital tools” OR “telehealth” OR “Internet of Things” OR “EHR”)) AND (“nursing homes” OR “elderly” OR “geriatric” OR “inpatient home” OR “care facility” OR “nursing facilities” OR “nursing home” OR “aged care” OR “care home” OR “long-term care” OR “senior living center” OR “LTC”). Exact search strings for each database are documented in Multimedia Appendix 1.

The literature search was conducted across PubMed, Web of Science, ProQuest, and the ACM Digital Library. These databases were selected to ensure broad interdisciplinary coverage of nursing, health care, and technology-related research. Gray literature was not searched systematically. However, 1 relevant report identified through manual search [45] was used to provide contextual information for the discussion and was not part of the primary evidence base.

Although specialized databases, such as CINAHL, were not included due to missing license at University of Applied Sciences Neu-Ulm, the chosen databases offer considerable overlap. This limitation and the potential risk of missed studies are acknowledged in the *Discussion* section. To enhance comprehensiveness, the database search was supplemented by citation tracking and manual searches. Searches were limited to the period from January 1, 2010, to December 31, 2024. As noted previously, 1 of the included studies [39] falls outside the formal inclusion window set; however, it was retained based

XSL•FO
RenderX

on discussions among all internal reviewers involved and due to the fact that this study represents the first known empirical study with the focus on the acceptance of digital technology among nursing staff in LTC settings. The identification process is illustrated in the PRISMA 2020 flow diagram, in the *Results* section.

The systematic search was conducted on April 14, 2025, following an initial exploratory search for an overview of the existing literature on October 25, 2024 (Multimedia Appendix 2). The primary researcher (JI) led the systematic review process, including database search, screening, and data extraction. The second reviewer (RH) independently screened the publications and also evaluated them for eligibility. Any discrepancies or critical assessments concerning study relevance, methodological quality, or thematic clarity were discussed in regular virtual meetings with senior reviewers (WS) and (DH). To manage the studies, the open-source software Zotero, version 7.0.11 (64-bit) was used as the reference software.

Study Selection

Study selection was conducted in 2 phases. The first phase was the selection via title and reading the abstract. In the second phase, the full texts of potentially eligible studies were reviewed in detail. Studies that met the inclusion criteria and passed quality checks were included in the synthesis. Excluded studies and reasons for exclusion are presented in Multimedia Appendix 3.

Due to the limited number of eligible studies, a formal sensitivity analysis was not possible. However, the impact of study quality on synthesis outcomes was qualitatively assessed during reviewer discussions.

Data items from included studies were extracted with the following variables using an Excel form:

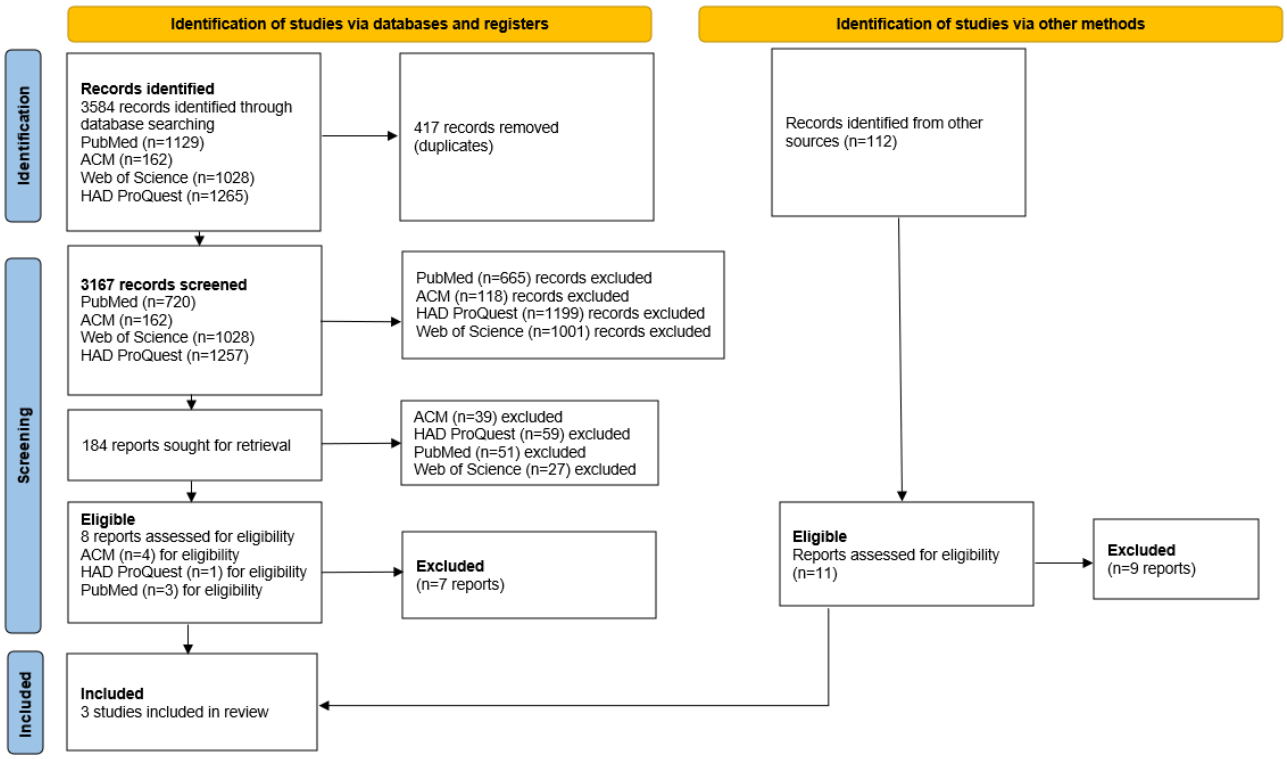
- Study identification: authors, title, year of publication, country
- Study design: methodological approach
- Participants: number, role (nursing staff, management)
- Aim of study: nature of the digital technology studied
- Key findings: outcome measures, determinants, and facilitators affecting acceptance

Quality Assessment

Methodological quality was assessed using the Critical Appraisal Skills Programme (CASP) [46], applying item-level judgments ("Yes," "Can't tell," "No"). The overall confidence rating was categorized as "low," "moderate," or "high," with no studies falling into the "high" category. Each study was independently assessed by 2 reviewers across all checklist domains, including study aims, design, recruitment strategy, data collection, analysis, and potential bias. Discrepancies between the reviewers were resolved through consensus. To further strengthen methodological rigor and confirm the reliability of the CASP-based evaluations, the AXIS (Appraisal tool for Cross-Sectional Studies) [47] checklist for cross-sectional studies was additionally applied as a supplementary framework (Multimedia Appendix 4).

Synthesis Approach

With regard to the synthesis approach, due to the heterogeneity of the included studies (technologies, outcome measures, countries), a narrative synthesis approach was applied keeping in mind the principles of thematic content analysis [48]. Data were coded inductively to identify recurring themes related to determinants and facilitators of digital technology acceptance. These themes were subsequently compared and mapped to ensure conceptual coherence across studies [49]. As this review analyzed previously published studies, no ethical approval was required.



Results

Study Selection

The outcome of the literature search initially yielded 3584 records from the databases and an additional 112 studies from citation tracking and manual searching as demonstrated in Figure 1.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram—identification of studies.

After the removal of duplicates, the screening of the studies, and the application of eligibility criteria, 3 studies were included in the final analysis [12,26,39]. The included studies reported quantitative findings using the following measures:

- Likert-scale derived scores: these were used in all studies to assess acceptance variables (eg, attitudes, fears, perceived usefulness).
- Regression coefficients: these were reported in Barisch-Fritz et al [12] and Yu et al [39] to identify predictors of acceptance (eg, age, gender, professional group).
- Descriptive statistics: frequencies, means, and standard deviations were commonly used to present the results.

For this study, qualitative studies were eligible; however, none were identified for the final selection. Although limited in number, these studies offer initial insights into key acceptance factors and provide a basis for further investigation. These studies were conducted in Germany, the Netherlands, and Australia. Together, they involved 1019 participants, most of whom were direct care workers in nursing homes or LTC facilities. Across all studies, 867 were nursing staff, 99 were nursing home managers, and 53 were other staff members in LTC facilities (eg, clerks). The technologies under investigation ranged from electronic documentation systems to assistive robotic devices and digital communication platforms.

Risk of Bias

The risk of bias was assessed using the CASP checklist for cross-sectional studies (Table 2). Individual checklist items were evaluated qualitatively to appraise methodological rigor, and each cell in Table 2 represents the reviewer's consensus.

XSL•FO
RenderX

Table . Critical Appraisal Skills Programme (CASP) evaluation.

CASP	Barisch-Fritz et al (2023) [12]	de Veer et al (2011) [26]	Yu et al (2009) [39]
1. Did the study address a clearly focused issue?	Yes	Yes	Yes
2. Did the authors use an appropriate method to answer their question?	Yes	Yes	Yes
3. Were the subjects recruited in an acceptable way?	Yes	Yes	Cannot tell
4. Were the measures accurately measured to reduce bias?	Cannot tell	No	Yes
5. Were the data collected in a way that addressed the research issue?	Yes	Yes	Yes
6. Did the study have enough participants to minimize the play of chance?	Cannot tell	Yes	Cannot tell
7. How are the results presented and what is the main result?	Yes	Yes	Yes
8. Was the data analysis sufficiently rigorous?	Yes	Yes	Yes
9. Is there a clear statement of findings?	Yes	Yes	Yes
10. Can the results be applied to the local population?	Cannot tell	Yes	Cannot tell
11. Is the research valuable?	Cannot tell	Yes	Yes

While the CASP checklist provided a structured approach to appraising methodological quality, we also considered the AXIS critical appraisal tool, and it confirmed the initial CASP-based judgments.

Two studies [12,39] were rated as having moderate risk of bias. The study by Barisch-Fritz et al [12] addressed a clearly focused issue using validated instruments. Although the sample was good, it was not randomly selected, introducing potential self-selection bias. The study by Yu et al [39] also had a moderate risk of bias. It demonstrated strong internal validity through the use of validated TAM2-based instruments and a clearly defined research aim. However, some limitations remain; for instance, the convenience sampling reduced the strength of the recruitment process. Also, the relatively small sample size limits generalizability. These facts increase the potential for selection and sampling bias. The study by de Veer et al [26] demonstrated low risk of bias, supported by transparent reporting and robust measurement design. Nevertheless, the study lacked detailed information on how bias was addressed through measurement design.

Study Characteristics

The key findings and characteristics of the included studies are summarized in Table 3. Across the 3 studies, several patterns emerged regarding the implementation and acceptance of technology in nursing and LTC settings. In the study by de Veer et al [26], approximately half of the nursing staff had encountered new technologies within the past 3 years and generally perceived these introductions positively. However, actual use was hindered by technology-related factors, such as ease of use, patient relevance, and potential risks. Respondents emphasized the need for structured innovation strategies and organizational support. Similarly, Yu et al [39] in Australia confirmed the validity of a modified TAM2 model for LTC facilities, identifying perceived usefulness, ease of use, professional image, and computer skills as primary determinants of the intention to adopt health IT applications. The German nationwide survey by Barisch-Fritz et al [12] extended these findings, showing that acceptance and technology affinity depend on education, professional role, and sociodemographic characteristics. Lower acceptance was observed among older employees.

XSL•FO
RenderX

Table . Included studies: key findings.

Authors	Title	Year of publication	Research method	Country	Aim of study	Which technology?	Participants included	Key findings
de Veer et al [26]	Successful implementation of new technologies in nursing care: a questionnaire survey of nurse-users	2011	Questionnaire survey	The Netherlands	To gain a better understanding of determinants influencing the success of the introduction of new technologies as perceived by nursing staff	• New technologies introduced in the past three years • Electronic information systems • Distant care technology • Medical devices	• 685 nursing staff	• Half of the respondents were confronted with the introduction of new technology in the past 3 years • Half of them rated the introduction of the technology as positive • Factors impeding actual use were related to the technology itself: ie, malfunctioning, ease of use, relevance for patients, risk to patients • Nursing staff stressed the importance of an adequate innovation strategy

Authors	Title	Year of publication	Research method	Country	Aim of study	Which technology?	Participants included	Key findings
								• Positive consequences depended on education and professional group and the affinity for technology varied across age and gender • Lower acceptance with increasing age • Lower acceptance for females • Lower acceptance among nursing home managers

[a]LTC: long-term care.

[b]TAM2: technology acceptance model.

Despite differences in geographic context and methodological design, the studies share some overlapping findings regarding common factors that influence the acceptance. Perceived usefulness and perceived ease of use [26,39] consistently emerged as important determinants of acceptance. In addition, digital competence, defined as the ability to interact confidently with digital tools, was positively associated with willingness to use technology, particularly among younger staff members [12]. Organizational support, including leadership endorsement, training opportunities, and the involvement of staff in decision-making processes, also acted as a strong facilitator [26].

These cross-cutting themes are summarized in Table 4, which illustrates the main factors affecting the acceptance across studies.

XSL•FO
RenderX

Table . Factors affecting acceptance.

Authors	Title	Year of publication	Strengths	Weaknesses	Practical relevance	Factors affecting acceptance
de Veer et al [26]	Successful implementation of new technologies in nursing care: a questionnaire survey of nurse-users	2011	Strategic depth, very practical, multisectoral representativeness	• Little quantitative analysis • Mainly qualitative; not 100% LTC-specific[a]	Very high: helpful for implementation planning, LTC sector, and hospital	• Involvement of nursing staff during development and implementation affects acceptance. • Organizational support, such as leadership endorsement, communication, and available training does increase adoption. • Perceived relevance of the technology for patient care enhances likelihood of use.
Yu et al [39]	Health IT acceptance factors in LTC facilities: a cross-sectional survey	2009	Theoretically grounded, structural modeling, clear implications	• Limited representativeness, convenience sample, preimplementation data	Moderate to high: theoretical insights; limited practical transferability relevant for IT strategies in the LTC context	• Perceived usefulness is the strongest predictor of care staff intention to use digital technologies. • Digital competence correlates positively with willingness to use technology, particularly among younger staff. • Negative perceptions through IT use (image factor) reduce acceptance. Ease of use significantly influences both perceived usefulness and intention to adopt technology. • Perceived relevance of the technology for patient care enhances likelihood of use.

RenderX

Authors	Title	Year of publication	Strengths	Weaknesses	Practical relevance	Factors affecting acceptance
Barisch-Fritz et al [12]	Are nursing home employees ready for the technical evolution? German-wide survey on the status quo of affinity for technology and technology interaction	2023	Good sample, valid measurement instruments, differentiated results	• Confounder control • Nonrandom sampling, response bias likely	High: directly applicable to nursing homes	• Digital competence correlates positively with willingness to use technology, particularly among younger staff. • Technology affinity varies strongly across age, gender, and professional role. • Organizational support, such as leadership endorsement, communication, and available training does increase adoption. • Ethical concerns can limit technology acceptance.

[a]LTC: long-term care.

All 3 studies contributed important evidence regarding factors influencing acceptance, organizational support, training availability, perceived usefulness, and digital competence. To account for heterogeneity across technologies and study designs, the extracted data were grouped thematically into 3 analytical levels: individual, organizational, and technological (Table 5).

This comparative thematic structure enabled a coherent synthesis across diverse contexts. Perceived usefulness, digital competence, organizational readiness, and usability emerged consistently across studies, supporting central constructs of the TAM.

XSL•FO
RenderX

Table . Thematic synthesis of factors affecting acceptance.

Level	Technology type	Emerging themes	Example evidence	Studies contributing
Individual	Electronic information and documentation systems; telecare software	Digital literacy, perceived usefulness, professional image, computer self-efficacy	Staff with higher digital competence and positive attitudes toward electronic documentation and telecare reported higher acceptance. Perceived usefulness and ease of use predicted intention to adopt these systems.	Barisch-Fritz et al (2023) [12] ; Yu et al (2009) [39]
Organizational	EHR[a] systems; digital readiness tools	Training, managerial support, workload, innovation climate	Organizational readiness, management involvement, and access to training facilitated technology use, while workload and lack of structured implementation strategies reduced uptake.	de Veer et al (2011) [26]; Barisch-Fritz et al (2023) [12]
Technological	Assistive technologies; robots; health IT software	Usability, reliability, system relevance, perceived ethical and professional implications	Usability and reliability were decisive for acceptance across all technologies, whereas assistive and robotic technologies introduced concerns regarding trust, ethics, and role identity.	de Veer et al (2011) [26]; Yu et al (2009) [39]; Barisch-Fritz et al (2023) [12]

[a]EHR: electronic health record.

Discussion

Interpretation of Findings

The synthesis of the 3 studies revealed that the acceptance of digital technologies in geriatric LTC depended on a combination of individual and organizational factors. Consistent with TAM and its extensions, usefulness and ease of use were the most robust predictors across the studies.

Beyond individual and organizational determinants, contextual factors, such as organizational culture, leadership style, and national policy frameworks, also influence digital readiness in LTC. Environments with a long-standing emphasis on innovation and participatory care culture may facilitate staff involvement in digital implementation, whereas strict data-protection orientation and reliance on paper-based processes may hinder the change. National eHealth infrastructures, such as Germany's Telematics Infrastructure and reimbursement policies, can affect incentives for adoption. Recognizing these dimensions is essential, as technological acceptance should not be understood in isolation from broader policy and organizational environments [50].

Previous reviews have also highlighted the importance of user attitudes and digital competencies for successful implementation [51-53]. Staff who feel confident in their ability to use digital tools are more willing to adopt them. This is particularly relevant given the generational differences observed in digital affinity. Younger staff members tend to have higher levels of acceptance, while older staff may require more training and support.

Organizational conditions further contribute to acceptance. Early staff involvement in the selection, testing, and implementation of new technologies, combined with training and transparent communication, fosters adoption.

A valuable complement to the peer-reviewed evidence is the BGW report "Pflege 4.0" [45], which constitutes gray literature but offers important contextual insights. Drawing on a mixed methods dataset of 576 professional caregivers in Germany—140 of whom were from geriatric LTC facilities—the report explored both actual technology use and perceived barriers to adoption. Using various 5-point Likert scales (ranging from "does not apply" to "fully applies"; from "not familiar at all" to "very familiar"), the survey identified key concerns, such as fear of job loss, data protection concerns, lack of technical skills, and low participation in implementation processes. While the professional composition of respondents was not fully specified, the findings add practical relevance by highlighting workplace-level perceptions that mirror those reported in the peer-reviewed studies.

Limitations of Evidence

The limited number (n=3) of eligible studies and their predominantly cross-sectional nature restrict the ability to draw clear conclusions, even though they identify relevant influencing factors. Additionally, the studies differ in the types of technologies investigated, outcome measures used, representation of demographic groups, and regional contexts. This heterogeneity complicates direct comparisons, and it further limits the generalizability of the findings. For instance, Yu et al [39] conducted a preimplementation survey based on TAM2 in an Australian LTC context, focusing on intention to use the technology. On the other hand, de Veer et al [26] investigated actual technology implementation across multiple health care sectors in the Netherlands, including nursing homes, but not exclusively. Barisch-Fritz et al [12] explored technology affinity in German nursing homes, but their heterogeneous sample included managers and other staff in LTC facilities with a

XSL•FO
RenderX

relatively small response rate. This fact raises concerns regarding representativeness. These limitations hinder generalizability.

Although comprehensive efforts were made to include all relevant research, the review was limited to publications in English or German, and no protocol was registered in advance. In addition, the CINAHL database was not searched due to a missing institutional license. As CINAHL is a relevant source, other studies may not have been captured.

Implications

Given the limited number of studies and their methodological heterogeneity, the implications hereby should be interpreted with caution. Nevertheless, the evidence indicates that the successful implementation of digital technologies in geriatric LTC relies on strategies that are aligned to the needs, competencies, and experiences of nursing staff. Policies should prioritize ongoing digital training programs based on the different groups of users. Furthermore, implementation efforts should involve staff from the earliest planning stages, ensuring that their expertise informs both system design and rollout. Organizational support and transparent communication regarding the objectives, benefits, and limitations of new systems are essential to build trust and reduce uncertainty among nursing staff. Ethical concerns must be addressed proactively, particularly in relation to surveillance technologies and the preservation of interpersonal care dynamics. In terms of research, there is definitely a need for more robust, rigorous, and longitudinal studies to enhance external validity and provide a more comprehensive understanding of technology acceptance among nursing staff in geriatric LTC.

Conclusion

This systematic review demonstrates that the acceptance of digital technologies by nursing staff in geriatric LTC settings is shaped by a constellation of individual and organizational factors. Three key determinants emerged consistently across all studies.

First, digital competence significantly influences willingness to adopt new technologies. Nursing staff with higher digital affinity, especially younger staff members, show greater readiness to engage with digital tools in the workplace. This highlights the need for training programs that target all age and experience groups.

Second, perceived relevance of technologies to daily care practice affects acceptance. Nursing staff are more likely to accept innovations that support main aspects of nursing home care, such as documentation efficiency, communication, or safety.

Third, organizational support, including communication, managerial encouragement, access to training, and staff participation in the implementation processes of digital technologies, plays a crucial role.

In light of the structural and demographic relevance of geriatric LTC, future research should be directed toward building a strong evidence base on technology acceptance. This review offers several testable hypotheses derived from the synthesized evidence. Future studies should empirically examine how early involvement of nursing staff in the development and implementation of digital technologies affects subsequent acceptance and sustained use. It can be hypothesized that organizational support mechanisms, including leadership endorsement, effective communication, and targeted digital training, strengthen the relationship between perceived usefulness and intention to use. Likewise, digital competence may mediate the relationship between training and technology adoption, while factors such as technology affinity, age, and professional role may moderate these effects. Furthermore, perceived relevance for patient care likely increases acceptance by reinforcing the perceived usefulness of digital tools, whereas ethical concerns or a negative professional image of IT use may inhibit adoption. Testing these mechanisms through longitudinal, intervention-based, or multilevel study designs could provide stronger causal evidence for the transformation strategies in geriatric LTC.

Acknowledgments

JI and the coauthors would like to thank Dr Felix Holl from Hochschule Neu-Ulm and also Amela (Gjoni) Brechlin, BA, from the nursing home St. Elisabeth Pflegezentrum gGmbH in Senden for the interesting discussions and the experience shared with regard to this topic.

Authors' Contributions

JI, WS, and DH participated in the design of the study. JI conducted the search. JI and RH were responsible for the screening of the results. JI, WS, and DH reviewed, evaluated critically, and edited the manuscript. All authors read and approved the final version of the manuscript.

Abstract

Background: Artificial intelligence (AI) tools are increasingly used in clinical settings, yet most syntheses focus on nurses' attitudes or readiness rather than experiences after direct use in practice.

Objective: This study aimed to synthesize registered nurses' experiences of using AI in clinical practice and to identify perceived benefits, barriers, and implementation implications.

Methods: We conducted a systematic literature review of empirical studies reporting nurses' experiences of AI use in clinical settings. Searches were performed in CINAHL, Embase, MEDLINE, PsycINFO, and PubMed (last search: September 13, 2023). Moreover, 2 reviewers (AJSS and QZ) independently screened titles, abstracts, and full texts and appraised included studies using the Mixed Methods Appraisal Tool. We used thematic synthesis with a primarily deductive framework based on the Technology Acceptance Model 2, with the addition of facilitating conditions from the unified theory of acceptance and use of technology.

Results: In total, 20 studies met the inclusion criteria. Perceived usefulness and facilitating conditions were most frequently reported; nurses described AI as supporting decision-making, workflow efficiency, and confidence when implementation included adequate training, interoperability, and technical infrastructure. Ease of use was closely tied to interface design and training. Job relevance and output quality were rated more positively when nurses described AI as aligning with nursing tasks and as producing interpretable, reliable outputs. Common barriers included usability issues, limited integration into workflows and electronic systems, privacy and trust concerns, and inconsistent or poorly contextualized outputs. Across studies, nurses often described adoption as conditional on organizational readiness and meaningful involvement of nurses in design and implementation.

Conclusions: Nurses' accounts suggest that AI may augment clinical work, but the perceived benefits reported in the included literature were contingent on workflow alignment, usable interfaces, training, and supportive infrastructure. These findings suggest potential value in involving nurses in the co-design and iterative refinement of AI tools, grounded in the consistent evidence that facilitating conditions, such as training, interoperability, and organizational readiness, are the primary determinants of whether AI is experienced positively. Prospective evaluation using nursing-relevant outcomes, such as usability, workflow integration, and trust, is needed to move beyond post hoc experiential accounts and establish what implementation conditions reliably produce benefit.

Introduction

The integration of artificial intelligence (AI) into health care has transformed clinical practice, significantly impacting the roles and responsibilities of registered nurses (RNs). As the largest group of health professionals, RNs are at the forefront of these technological shifts and have historically been an afterthought in technology development [1]. AI holds significant potential to enhance nursing practice in administration, clinical practice, policy, and research, but it remains an area of ongoing exploration [2]. For example, natural language processing

XSL•FO
RenderX

systems are increasingly used to assist with clinical documentation, decision support algorithms enhance diagnostic reasoning, and in nursing administration, AI has been applied to workload prediction and staff scheduling, while in research, it supports pattern recognition in large datasets [3].

AI's emergence in health care has altered nursing roles, workflows, and the nurse-patient relationship [4,5]. Technologies like predictive analytics, virtual health care assistants, and robotics are influencing nursing practice in substantive ways: (1) predictive analytics supports early identification of deteriorating patients, enabling more proactive clinical intervention; (2) virtual health care assistants facilitate patient education and remote monitoring; and (3) robotic technologies are increasingly used for medication dispensing and patient mobility support, reshaping how physical tasks are distributed [6-8]. While these AI-driven technologies offer improvements in health care delivery, they also challenge the maintenance of person-centered, compassionate care [2]. AI already contributes significantly to decision-making support and skill augmentation within clinical practice [9]. Nurses must proactively ensure AI technologies align with nursing's core values, maintaining ethical and compassionate care [10].

The integration of AI into nursing practice is accelerating, and existing systematic reviews predominantly explore general perceptions and theoretical readiness or educational readiness among nurses [11,12]. These studies offer valuable insight into anticipated benefits and challenges, yet conclusions are derived from nurses who have not directly interacted with AI in clinical settings. For example, 1 recent review synthesized qualitative studies focused on nurses' perceptions without requiring previous AI use [12]. Several recent reviews have examined AI specifically within nursing education contexts; one explored AI use in nursing training [13], while another synthesized empirical evidence on AI implementation in hospital settings using a strengths, weaknesses, opportunities, and threats framework [14], and another mapped AI applications, such as generative tools and virtual patient simulators, in university-level nursing programs [15]. All 3 address AI as a pedagogical resource for nursing students and trainees, rather than clinical practice. There remains a lack of synthesis of studies capturing nurses' attitudes after engaging directly with AI tools.

Several theoretical frameworks can be used to understand individuals' acceptance and use of technology, such as AI. The Technology Acceptance Model 2 (TAM2) is among the most extensively validated, proposing that perceived usefulness, perceived ease of use, and social and cognitive influences shape technology adoption [16]. TAM2 was developed in general organizational technology contexts, and we acknowledge that it may underweight dimensions that are particularly salient in nursing, including professional judgment, the nurse-patient relationship, ethical responsibility, accountability for patient outcomes, and the emotional and moral dimensions of clinical work. We selected TAM2 nonetheless because our review question concerned nurses' acceptance-relevant experiences after direct AI use, where TAM2's validated constructs provide an established and transparent analytic vocabulary. To address TAM2's primary acknowledged limitation, its limited treatment of organizational and infrastructural context, we incorporated the Facilitating Conditions construct from the unified theory of acceptance and use of technology (UTAUT) [17], which captures the technical, training, and resource conditions that nurses' accounts suggested were central to their experiences. We did not adopt the full UTAUT to avoid construct duplication with TAM2 (the implications of this deductive choice for what the synthesis could and could not surface are discussed in the Limitations section). This review explores the experiences of RNs navigating modern health care complexities, with a focus on AI's impact on nursing roles, the challenges in adapting to AI technologies, and how these changes are perceived to influence patient care using TAM2 and UTAUT's Facilitating Conditions as the analytical framework.

The research question guiding this systematic review is "What are the experiences of nurses using AI in their clinical work?" The objectives are to (1) develop a better understanding of how nurses interact with AI in clinical practice, and (2) provide insights into nurses' perceptions of AI's impact on efficiency, satisfaction, and nurse-patient relationships.

Methods

Overview

The primary objective of this systematic review is to understand the experiences of nurses using AI in clinical practice.

A systematic review methodology was selected because the research question required a comprehensive, transparent, and reproducible synthesis of empirical evidence from multiple studies. This approach is appropriate for identifying and integrating findings across a body of literature to address a focused question about a specific population's experiences, and is consistent with established guidance for evidence synthesis in health professions research [18].

Protocol and Registration

The study protocol was registered with PROSPERO (CRD42022308051) [19]. The manuscript title has been refined from the registered title for clarity; the review question, eligibility criteria, and methods are consistent with the registered protocol.

Ethical Considerations

Ethics approval was not required because this study synthesizes data from previously published literature and did not involve collection of identifiable participant data.

Eligibility Criteria

Eligibility was determined using predefined inclusion and exclusion criteria (Textbox 1).

XSL•FO
RenderX

Textbox 1. Eligibility criteria.

Inclusion criteria

- Empirical research published in English: to ensure consistency and enable thorough analysis, only studies published in English were included.
- Peer-reviewed journal articles: studies published in peer-reviewed journals were prioritized for their methodological rigor and reliability.
- Studies where registered nurses describe their experiences of using artificial intelligence (AI) in clinical practice: the review focused on direct, real-world experiences of registered nurses with AI technologies. For inclusion, studies were required to report on nurses' experiences or perceptions arising from actual use of or interaction with an AI tool in a clinical setting. Studies reporting only on anticipated, hypothetical, or theoretical attitudes toward AI, without confirmed direct use, were excluded.
- Non–peer-reviewed sources (such as poster presentations and conference abstracts): these would have been considered only if they contained unique empirical data not yet published in a peer-reviewed format and demonstrated methodological rigor as assessed using the Mixed Methods Appraisal Tool (MMAT) criteria applied to all included studies.

Exclusion criteria

- Studies published in languages other than English: non-English language publications were excluded due to language barriers affecting interpretation.
- Studies reporting the experiences of nurses using technology not underpinned by AI: studies reporting on technologies that were not underpinned by AI were excluded.
- Studies reporting the experiences of nurses working in non-clinical settings: research focusing on administrative, academic, or educational settings outside of clinical practice were excluded.
- Studies related to health care professionals (eg, midwives and doctors): studies were excluded unless they specifically reported data related to registered nurses.
- Duplicate reports of the same study: the most comprehensive versions of duplicate studies were included.

Information Sources

A comprehensive literature search was conducted on September 13, 2023 across 5 electronic databases—PubMed, Embase, MEDLINE, CINAHL, and PsycInfo.

Search Strategy

A search strategy was developed and refined through repeated testing and adjustment, using both keywords and controlled vocabulary tailored to each database. Concept blocks, illustrated in Textbox 2, provided the structure for the search, with keywords and controlled vocabulary terms merged using Boolean logic (AND/OR) to ensure comprehensiveness. No date restrictions were applied, allowing for the inclusion of all eligible studies up to the date of the search. Searches were not restricted by language, but inclusion was limited to studies published in English. Reference lists of identified articles were also reviewed, but no additional studies met the inclusion criteria. Full search strategies are provided in Multimedia Appendix 1.

Textbox 2. Search strategy concept blocks.

Block 1: Nursing

- Keywords: Nurse* (Title or Abstract), "Nursing staff" (Title or Abstract), "Nursing professional*" (Title or Abstract), "Registered nurse*" (Title or Abstract)
- CINAHL Headings: Nurses, Nursing Staff

Block 2: Artificial intelligence

- Keywords: "Artificial Intelligence" (Title or Abstract), "Machine Learning" (Title or Abstract), "Neural Network*" (Title or Abstract), "Deep Learning" (Title or Abstract), "Computer Vision" (Title or Abstract), "Natural Language Processing" (Title or Abstract)
- CINAHL Headings: Artificial Intelligence, Machine Learning

Block 3: Experiences or perceptions

- Keywords: Experience* (Title or Abstract), Perception* (Title or Abstract), View* (Title or Abstract), Attitude* (Title or Abstract), Feedback (Title or Abstract), Opinion* (Title or Abstract)
- CINAHL Headings: Attitude, Perception

Study Selection

The review was conducted following the Joanna Briggs Institute (JBI) methodology for systematic reviews, using the "JBI Manual for Evidence Synthesis" [20] as the guiding framework. The reporting of this review adheres to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines [21]. Study management and screening were managed with Covidence software (Veritas Health Innovation Ltd). Furthermore, 2 reviewers (AJSS and QZ) independently

XSL•FO
RenderX

screened titles, abstracts, and full texts, resolving discrepancies through discussion and consensus. In cases where multiple reports of the same study were identified, the most comprehensive version was prioritized, and duplicates were merged accordingly. The screening and selection process are presented in the PRISMA flow diagram in the Results section. The completed PRISMA 2020 checklist is also provided in Checklist 1.

Data Extraction

Data extraction followed the JBI mixed methods data extraction form following a convergent integrated approach [20]. Where studies included multidisciplinary samples, nurse-specific findings were extracted separately where the primary data permitted. In cases where profession-specific disaggregation was not possible, this was noted explicitly in the data extraction table (Multimedia Appendix 2).

Quality Appraisal

Study quality was assessed using the Mixed Methods Appraisal Tool (MMAT) [22] to accommodate the diversity of included study designs. This aligned with the convergent integrated approach used in this review [20]. Additionally, 2 reviewers (AJSS and QZ) independently assessed study quality, and any discrepancies were resolved through discussion to reach consensus. To capture the complexity of interpretive and critical understandings of AI use in nursing, an inclusive approach to study selection was maintained. As noted by Hannes and Lockwood [23], qualitative evidence can simultaneously illuminate both broad patterns and context-specific detail, and excluding studies entirely based on quality grounds risks narrowing this breadth. Including all studies regardless of MMAT scores allowed for a representative synthesis across diverse clinical contexts. Quality appraisal results were therefore used to inform the interpretation of findings, rather than as a basis for exclusion. Where lower-quality studies contributed to a construct, this is noted within the relevant Results section.

Synthesis Approach

Thematic analysis was conducted using a predefined deductive framework based on TAM2, supplemented by the single UTAUT construct of Facilitating Conditions. All included studies were read in full, and relevant text segments, including direct participant quotations, authors' qualitative summaries, and quantitative findings, were coded line-by-line into the framework constructs. Coding was undertaken by the first author (AJSS), with regular review and discussion of coding decisions with 2 supervising coauthors (BCB and DD) throughout the analysis period. These supervisory discussions served as a calibration mechanism for the application of the codebook; ambiguous extracts and decisions about construct boundaries were brought to these meetings, discussed against operational definitions, and resolved by consensus before being applied across the dataset. The codebook (Table 1) was iteratively refined through these discussions to clarify operational boundaries; construct categories themselves remained fixed throughout. Formal interrater agreement was not calculated, as only a single author (AJSS) coded the data; this is acknowledged as a limitation. Quantitative findings relevant to TAM2 constructs, such as survey results, were summarized and integrated narratively with the qualitative data under relevant headings. Where frequency of reporting is described, this refers to the number of included studies in which relevant data were coded to a given construct. Frequency counts indicate how commonly a construct appeared across the included studies and should not be interpreted as a measure of the depth or strength of any individual theme.

Table . Codebook adapted from TAM2[a]+UTAUT[b].

Construct	Definition (as applied in this review)
Perceived usefulness	• Excerpts where the AI[c] is seen as having an impact on job performance. • Statements indicating that the AI impacts the effectiveness of task completion or enables more task opportunities. • Examples of how AI is perceived to enhance patient care or nursing outcomes.
Perceived ease of use	• Descriptions of how the AI is straightforward and easy to use or interact with. • Quotes about the learning curves in relation to using AI in practice. • Facilitators or challenges related to technical aspects of interacting with the AI.
Subjective norms	• Comments about how the organization, management, or colleagues influence attitudes toward AI. • Encouragement or pressure from peers to use or not use AI. • The role of policy supporting or discouraging AI use.
Intention to use	• Nurses' statements related to plans or indications to use AI in the future. • Motivating or deterring factors relating to the intention to use AI in practice. • Conditional intentions (eg, willingness to use AI if specific supports or changes are implemented).
Usage behavior	• Discussions of actual use or engagement with AI in practice. • Context, duration, and frequency of AI use in practice. • Examples of tasks or procedures where AI is being implemented.
Facilitating conditions[d]	• Technical or organizational infrastructure supporting the use of AI. • Availability or lack of resources like support staff, training, and technical expertise. • Compatibility of the AI with existing systems and workflows.
Job relevance	• To what degree do nurses think AI is relevant to their job. • Specific responsibilities or tasks that are impacted by AI. • Changes in responsibilities or job roles as a result of AI integration.
Output quality	• Perceptions of quality of the results provided by AI systems. • AI's impact on the overall quality, timeliness, and accuracy of nursing care. • Consistency and reliability of AI outputs.
Result demonstrability	• Visibility and tangibility of results of using AI in nursing practice. • Examples of observable and clearly articulated benefits or drawbacks of AI use. • Stories demonstrating the impact of AI use on patient outcomes or nursing practice.

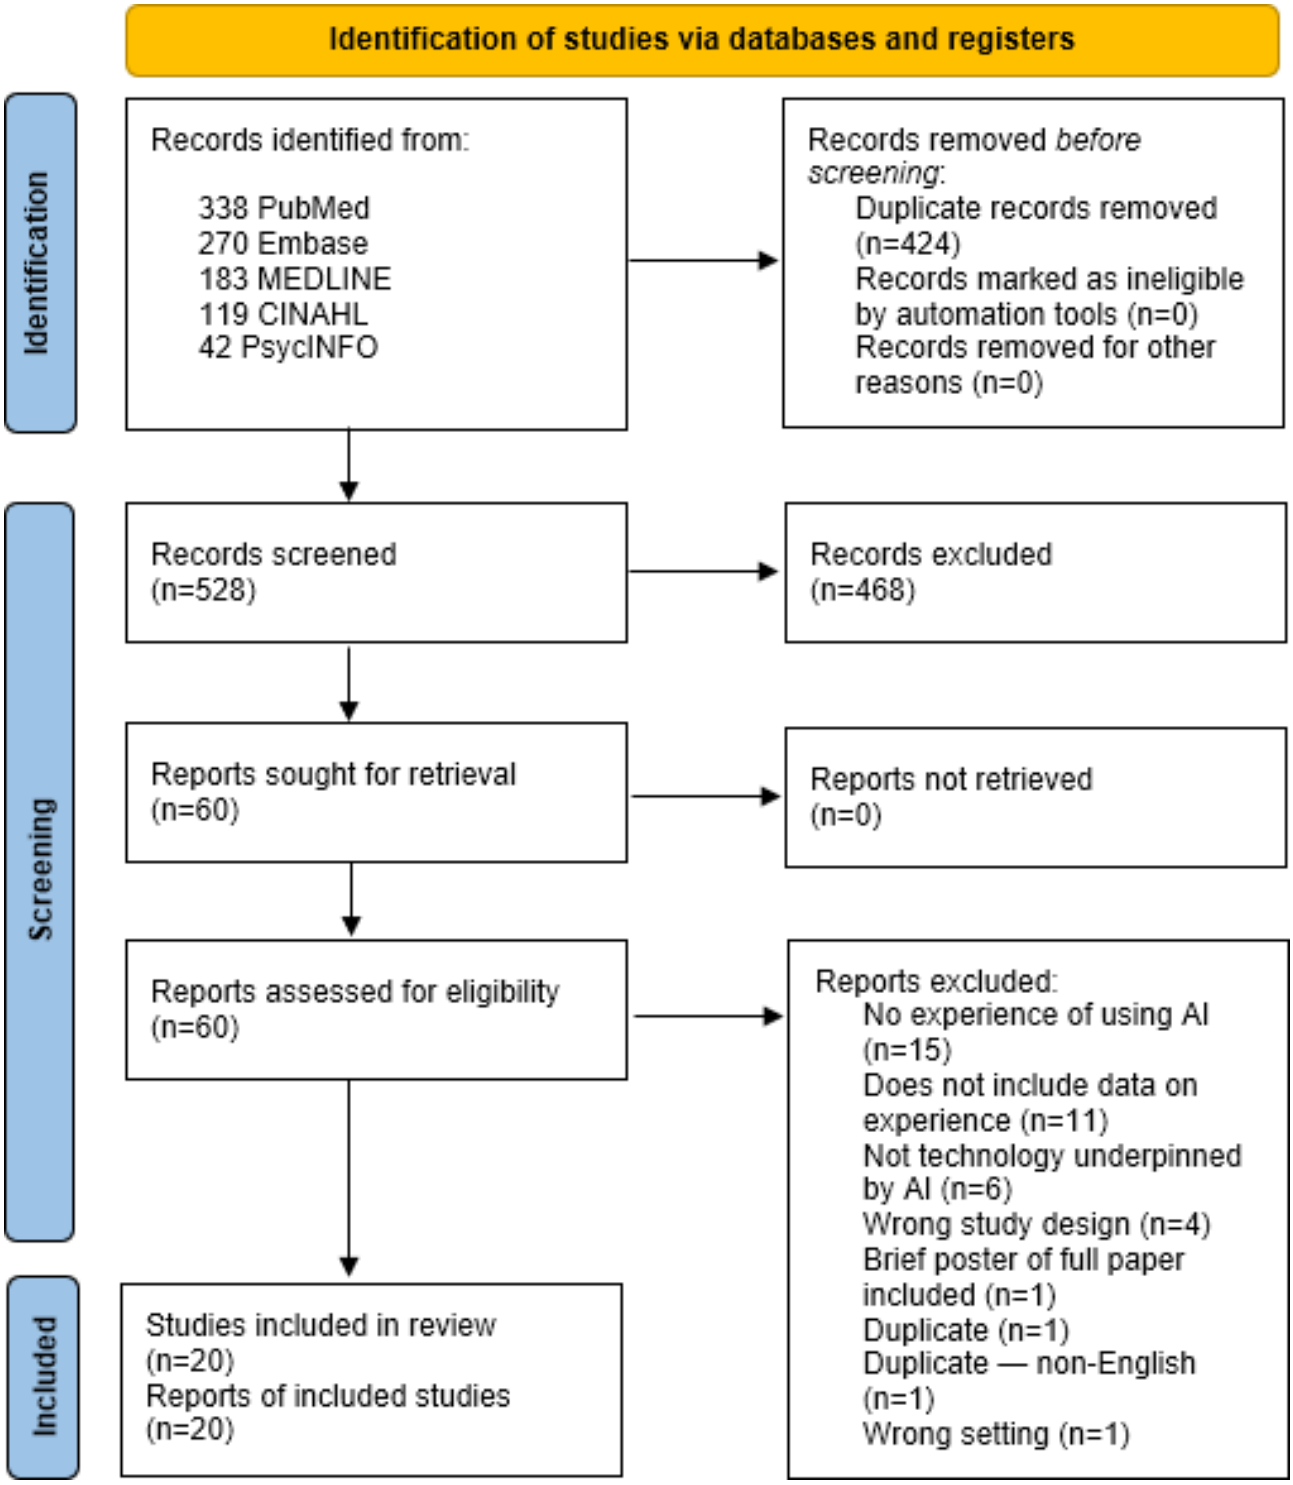
Results

Study Selection

The PRISMA flow diagram (Figure 1) is presented to illustrate the screening and selection process. The initial searches yielded 952 records. After 424 duplicate or merged records were removed in Covidence, 528 articles were screened by title and abstract. Of these, 60 reports were sought for retrieval and assessed for eligibility, resulting in the exclusion of 40 reports for reasons such as the lack of AI experience (n=15), lack of experiential data (n=11), a focus on non-AI technology (n=6), and other contextual or methodological reasons as detailed in Multimedia Appendix 3. Ultimately, 20 studies [24-43] met the inclusion criteria and were included in the final synthesis.



XSL•FO
RenderX

Of the 20 included studies, 13 were appraised as high quality [31-43], 5 as medium [24-28], and 2 as low [29,30] (Multimedia Appendix 4). The 5 medium-rated studies were predominantly quantitative surveys with limitations relating to sampling representativeness and nonresponse bias [24-28]. The 2 low-rated studies had insufficient methodological reporting to fully assess rigor [29,30]. Job Relevance and Output Quality were supported exclusively or predominantly by high-rated studies. Perceived Usefulness was well-represented across quality levels but anchored by a majority of high-rated studies. Facilitating Conditions drew contributions from the broadest quality range, including both low-rated studies; findings for this construct are therefore interpreted with appropriate caution below.

Of the 20 included studies, the proportion of nurse participants varied substantially. Of the total, 9 studies reported that nurses comprised the majority of participants [24,25,29,31-36]. In the remaining studies, nurses participated alongside other professional groups, and in some cases were a small minority. While there was no requirement for studies to have a majority of nurse participants, this variability affects the extent to which findings directly reflect nursing perspectives. Where possible, data specific to nurses was extracted for synthesis. However, in several studies (eg, [26,34,37]) nursing data were supplementary or aggregated with other professions. A full summary of participant demographics and professional backgrounds is presented in Table 2.

Table . Characteristics of included studies.

Study (year)	Country and setting	Study design	Participants	AI[a] and technology focus
Alanzi (2023) [31]	Saudi Arabia, health care sector (government hospitals)	Qualitative, focus group interviews	Total: 54 participants • Physicians: 11 • Nurses: 24 • Dieticians: 8 • Pharmacists: 6 • Physiotherapists: 5 • Sex: 33 females, 21 males • Majority have more than 6 years of experience • Professions: physicians, nurses, dieticians, pharmacists, and physiotherapists	• ChatGPT
Belmin et al (2022) [27]	France, multicenter trial with community-dwelling adults receiving home care	Quantitative, uncontrolled multicenter pragmatic trial	• 206 community-dwelling older adults • Mean age: 85 (SD 8) y • Gender: 78% women • Age eligibility: ≥75 years • Health status: community-dwelling older adults with mild or moderate dependency (GIR 3 or 4) • Receiving care from 109 home aides	• eHealth system with a machine learning algorithm for predicting ED[b] visits • Decision support for predicting and reducing emergency department visits among older adults, patient monitoring, and optimizing care pathways
Boggiss et al (2023) [38]	Aotearoa, New Zealand, pediatric diabetes clinics and online communities	Qualitative, online focus groups, and one-on-one interviews	Total: 30 • Adolescents: 19 (adolescents aged 12-16 y with type 1 diabetes) • 58% female, 68% Aotearoa New Zealand European, 11% Māori • Living in Aotearoa, New Zealand • Diagnosis of type 1 diabetes for more than 6 months • No serious developmental or psychiatric disorders • Diabetes health care professionals: 11 (health care professionals from various disciplines, such as diabetes nurse specialists, health psychologists, dieticians, and endocrinologists)	COMPASS Chatbot (Expert System) • Psychological support and self-management assistance for adolescents with type 1 diabetes
Castagno and Khalifa (2020) [37]	London, United Kingdom, Royal Free London NHS Foundation Trust hospitals	Qualitative, web-based survey	Total: 98 • Medical doctor: 34 • Nurse: 23 • Manager: 11 • Therapist: 7 • Other: 23 • No demographic information was collected	General AI applications in medicine.

Study (year)	Country and setting	Study design	Participants	AI[a] and technology focus
Catalina et al (2023) [28]	Central Catalonia, Spain, primary care settings	Quantitative, observational cross-sectional study using a validated survey	Total: 301 • Mean age: 46.0 (SD 11.0) year • Sex: female (81.1%), male (18.9%) • Occupation: Nursing (47.8%), Medicine (48.5%), Others (3.65%) • Years of experience: More than 10 years (62.5%)	AI as a health care tool, with a specific focus on its impact on PC radiology.
Gardner and Lundsgaarde (1994) [24]	United States, LDS Hospital	Quantitative, observational study using a questionnaire survey	Total: 1320 • Physicians: 360 (aged 27-82 y, mean age 45.5 y) • Nurses: 960 (aged 20 to 67 y, mean age 33.57 y) • Nurses average professional experience of 9.52 years, with 6.96 years at LDS Hospital	Health Evaluation through Logical Processing (HELP). Expert system • Decision support, patient monitoring, and documentation assistance.
Ginestra et al (2019) [29]	Philadelphia, United States, 782-bed academic hospital	Mixed methods, prospective observational study. Surveys were deployed to collect qualitative data on clinicians' perceptions, and quantitative analysis was performed on the survey results	Total: 287 • Nurses: 180 • Providers: 107	Early Warning Score tool (EWS 2.0). Machine Learning. Decision Support and patient monitoring for sepsis.
Gonçalves et al (2020) [32]	Brazil	Experience report, direct observation, and semistructured interviews	Not clearly mentioned	Robot Laura. Machine learning. Decision support for identification of sepsis.

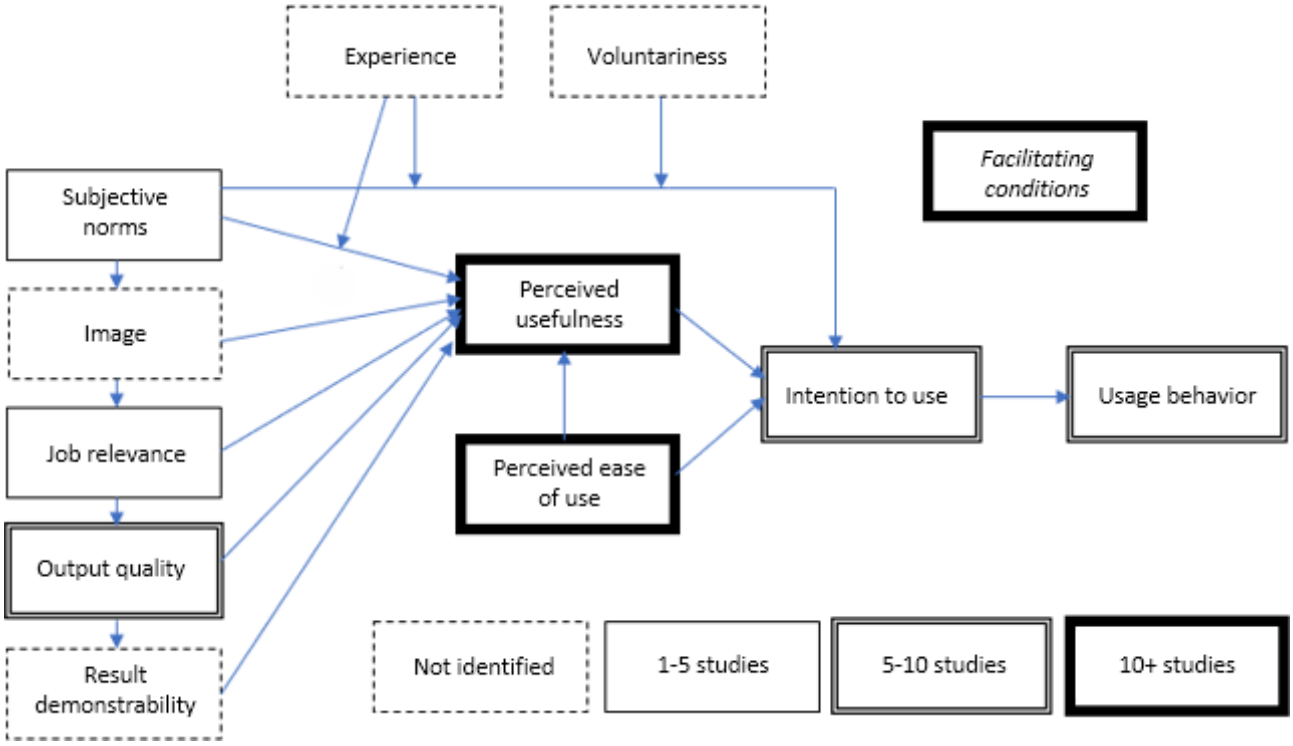
			Total: 43 • Physicians: 21 • Pharmacists: 14 • Registered nurses: 2 • Nurse practitioners: 1 • Physician's assistants: 5 • Specialties: internal medicine, neurology, cardiology, oncology or hematology, infectious diseases, endocrinology • Average years of practice: 10 years	
Sandhu et al (2020) [36]	Duke University Hospital, United States	Qualitative. Semistructured interviews, modified grounded theory approach	Total: 15 • ED Physicians: 7 • RRT Nurses: 8	Sepsis Watch. Decision support for early sepsis detection and monitoring in emergency departments. Machine learning.
Schwartz et al (2022) [43]	Massachusetts, United States	Qualitative. Semistructured interviews with content analysis	Total: 17 • Prescribing providers: 9 • Nurses: 8	CONCERN, predictive clinical decision support for in-hospital deterioration.

[a]AI: artificial intelligence.

[b]ED: emergency department.

Quality Appraisal



Using the MMAT [22], adherence to quality criteria ranged from strong methodological coherence [31,33] to studies with notable limitations such as unclear sampling strategies [27], lack of representativeness [26], and insufficient reporting of nonresponse bias [24,25]. Common issues included limited discussion of divergences between qualitative and quantitative findings in mixed methods studies [29,34], and a reliance on single data sources [37]. Detailed MMAT findings for each study are presented in Table S1 in Multimedia Appendix 4.

Synthesis of Findings

Findings from the included studies, grouped by TAM2 constructs, are summarized below and presented in detail in Multimedia Appendix 2. Figure 2 illustrates a conceptual map of the TAM2 and UTAUT constructs weighted by frequency of them being identified in the included studies.

XSL•FO
RenderX

Figure 2. Conceptual map of constructs weighted by frequency.

Perceived Usefulness

A total of 17 studies reported nurses' perspectives of AI as enhancing the effectiveness and quality of their work [24-27,29,31,33-43]. Reported benefits included earlier detection of clinical deterioration, improved triage and decision-making [29,35,36], more structured and efficient documentation [24,43], and enhanced patient-clinician communication [41]. As 1 nurse explained,

> [ChatGPT can help me in learning new developments in the telenursing process, especially in relation to the standards of practices, treatment or monitoring procedures. This helps me to improve my skills and capabilities and be up-to-date with the developments in the telenursing sectors, and provide high quality care to the patients remotely.] [31]

In some cases, AI tools contributed to professional confidence and visibility [32,35], with nurses describing the technology as a "safety net" in relation to their decision-making [35]. Perceived usefulness was mixed where the tangible benefits to workflow were unclear or where implementation was limited [34,39]. Furthermore, 3 contributing studies [26,34,37] involved multidisciplinary samples from which nurse-specific data could not be disaggregated; these studies are highlighted in Multimedia Appendix 2, and the nurse-attributed findings above are therefore drawn predominantly from the remaining 14 studies.

Facilitating Conditions

In total, 16 studies reported on facilitating conditions [24-26,28-31,33,35-41,43]. Common themes included access to adequate training, system interoperability, hardware availability, data privacy, and sufficient time within workflows. Willingness to adopt AI was often expressed as being conditional on meeting these facilitating factors [26,28,40]. For example, 1 nurse noted that,

> *Training was yet another organizational matter… not all participants had taken part in these sessions.* [39]

Nurses also requested integrated feedback mechanisms, such as dashboards and trend data [33,41], which highlights the importance of embedding technical support and continuous learning into implementation strategies.

This construct drew contributions from the broadest quality range of any major theme, including both low-rated studies [29,30] and 4 medium-rated surveys. Petitgand et al [30] additionally only involved 3 nurse participants within a predominantly physician sample. While the consistency of facilitating conditions findings across a large number of high-quality studies lends the construct overall coherence, the specific findings from lower-quality studies should be treated as indicative rather than definitive, and the low-rated studies should be interpreted in the context of their methodological limitations as documented in Multimedia Appendix 4.

Perceived Ease of Use

A total of 11 studies addressed perceived ease of use [24-26,28,30,34,36,38,40,42,43]. Nurses valued clear, straightforward interfaces and outputs [36,42], with structured displays facilitating interpretation [24]. As 1 nurse commented,

> *The nurses commented that their computer-printed charts were readable and understandable.* [24]

Barriers included slow system responses, limited interoperability, and difficulty editing records [24,26], as well as challenges interpreting model outputs, with nurses questioning "what have you done to change our processes? What have you done to improve the medical history?" [30].

XSL•FO
RenderX

Several studies noted that ease of use was closely tied to training and resources [28,38,40], which suggests that structured exposure supports both usability and uptake. Moreover, 4 of the contributing studies were medium-rated quantitative surveys, and 1 was rated low [30]; meaning findings on ease of use from these studies are less methodologically robust than those drawn from the high-rated qualitative studies, which provide the primary evidential basis for this construct.

Intention to Use

In total, 9 studies described nurses' intentions to use AI tools [24,27,33,35,39-43]. Intentions were generally reported as positive, with participants expressing interest in continuing or expanding use of AI, particularly with tools that supported decision-making, communication, or workflow efficiency. However, this willingness to adopt was often conditional on receiving adequate training and support, reflecting the critical role of preparatory education in facilitating adoption. All 9 contributing studies reported nurse-specific findings on intention to use, providing a clear nurse-attributable evidence base for this construct; quality ratings of contributing studies were predominantly high (7 high and 2 medium).

Use Behavior

In total, 8 studies described nurses' actual AI system use [24,26,27,29,34-36,43]. Usage ranged from integration into usual practice [36] to limited uptake during pilot testing [34]. Where AI was used, nurses described making changes to patient management and blending system outputs with their own expertise and clinical judgment [27,29]. Lower usage was usually linked to technical limitations, time constraints, or incomplete integration with existing systems. Of the 8 contributing studies, 6 reported nurse-specific use patterns; in 2 studies [26,34], profession-specific use could not be disaggregated and findings reflect aggregated clinician use behavior.

Output Quality

A total of 8 studies addressed perceptions of output quality [26,27,31,32,34,35,38,43]. High-quality outputs were described as accurate, relevant, and timely, supporting decision-making and patient care [27,35]. In contrast, neutral or mixed views emerged when outputs were perceived as unclear, lacked contextualization, or when usability issues were present [26,34]. Of the 8 contributing studies, 2 [26,34] involved multidisciplinary samples in which nurses' perceptions of output quality could not be separated from those of other clinical groups; the findings on output quality therefore reflect a combination of nurse-specific and broader clinician views.

Job Relevance

Of the total, 4 studies talked about job relevance [31,32,35,38]. Nurses could see a clear alignment with some core professional tasks, such as maintaining up-to-date clinical knowledge [31], supporting patient self-management [38], aiding early identification of sepsis [32], and enhancing triage decisions without replacing professional nursing expertise [35]. AI systems that aligned with existing nursing responsibilities appeared to reinforce acceptance and perceived value. All 4 contributing studies [31,32,35,38] were appraised as high quality on the MMAT and reported job relevance findings specific to nurses, providing the most consistently nurse-attributable evidence base of any construct in this review, albeit drawn from a small number of studies.

Subjective Norms

Of all, 2 studies contained discussion of subjective norms [27,32]. Positive attitudes toward AI among peers and team leaders were associated with greater acceptance, while involvement in the development process contributed to professional satisfaction and perceived status. These findings highlight the influence of workplace culture and peer endorsement in shaping AI adoption. Given that this construct was evidenced by only 2 studies, 1 high-quality qualitative study [32] and 1 medium-quality quantitative study [27], the latter with participant sample limitations including a low response rate, and given the limited evidential base overall, these findings should be treated as preliminary, with low confidence, and interpreted with caution.

Across the included studies, perceived usefulness and facilitating conditions emerged most frequently, highlighting nurses' focus on whether AI tools tangibly improve patient care and whether the necessary infrastructure and education are in place to support their integration. Perceived ease of use was also a fairly common theme, closely tied to training and ongoing support, suggesting that structured exposure to AI systems is essential for successful adoption. Job relevance and output quality were less frequently discussed but were positive when present, which reinforces the importance of aligning AI applications with core nursing tasks, as well as the need for them to deliver accurate, contextually relevant outputs. In contrast, subjective norms were only sparsely reported, indicating limited exploration of how peer attitudes and organizational culture shape adoption.

Discussion

Overview

This systematic review synthesized findings from 20 studies reporting RNs' experiences of AI in clinical practice. Nurses described AI as having the potential to support decision-making, workflow efficiency, and clinical confidence, although these reported benefits were consistently contingent on implementation quality. Perceived usefulness and facilitating conditions emerged as the most frequently reported constructs, with ease of use, workflow alignment, and organizational support recurring as determinants of whether nurses experienced AI as a benefit or a burden. Findings most directly attributable to nurses come from studies with majority nurse samples (notably for Job Relevance and several studies contributing to Perceived Usefulness), whereas constructs such as Output Quality, Subjective Norms, and elements of Facilitating Conditions drew partially on multidisciplinary samples; these are interpreted with caution below. Confidence in each finding is therefore not uniform; Job Relevance and Output Quality are anchored by high-quality studies, Perceived Usefulness is supported by a mostly high-quality evidence base, Perceived Ease of Use and Facilitating Conditions draw on a wider range of methodological quality, and Subjective Norms rests on the smallest and most heterogeneous evidence base.

XSL•FO
RenderX

Principal Results

Across the 20 included studies, nurses generally viewed AI as having the potential to improve clinical workflows and to contribute positively to care delivery, although the breadth of these perceptions varied by AI type and clinical setting. However, challenges were also evident, such as training needs, workload concerns, interoperability issues, and ethical considerations. While constructs such as perceived usefulness and facilitating conditions were frequently discussed, subjective norms and job relevance were less often explored, suggesting underresearched areas with potential to influence adoption.

Comparison With Previous Work

Perceived Usefulness

Findings from this review align with the broader AI in health care literature, in which clinicians have expressed optimism about AI's perceived capacity to support clinical tasks, improve efficiency, and contribute to patient care [44-46]. Nurses in the included studies valued AI for specific applications where they perceived benefits as tangible, such as clinical decision support or rapid information retrieval. However, these perceptions were contingent upon the technology being implemented in a way that integrated meaningfully into existing workflows and practice.

Perceived Ease of Use

Consistent with previous research, user-friendly design was a key determinant of willingness to adopt AI in nursing practice [5,47]. Positive experiences were associated with technologies that nurses described as streamlining workflows and reducing burden [48,49]. Conversely, steep learning curves, significant training demands, and inadequate integration led to frustration and resistance [48,50]. Ethical and social concerns, including privacy, trust, and algorithmic bias, were additional barriers [51,52]. These findings suggest that even with positive initial intentions to use AI, without adequate support, integration, and training, this may not translate into long-term adoption.

Subjective Norms

Although less frequently addressed in the included studies, subjective norms play a recognized role in technology adoption across contexts [53-55]. Positive cultural attitudes, leadership endorsement, and peer support could foster AI uptake among nurses. Educational settings represent an opportunity to shape these norms early by embedding AI exposure into curricula, normalizing its use, and developing confidence before clinical deployment.

Facilitating Conditions

Facilitating conditions emerged as critical to successful implementation. Key barriers included interoperability, data sharing, algorithm transparency, and infrastructure readiness [44]. Education and training were consistently identified as enablers [48,56,57]. Academic institutions can play a pivotal role by equipping future nurses with AI competencies and fostering a culture of informed, confident use. Embedding AI in training environments may help bridge the gap between intention and practice.

Job Relevance

While discussed less frequently, job relevance is important for long-term adoption. Concerns included overreliance on AI potentially diminishing nursing roles and the need to ensure AI complements rather than replaces nursing judgment. A proactive approach, where nurses adopt a positive stance toward technological integration [58], may enhance perceived relevance and strengthen the profession's role in shaping AI use.

Implications

Policy and Practice

Findings from this review reinforce that nurses view AI as a tool to supplement rather than replace clinical decision-making, a perspective echoed in previous research [1,59]. Buchanan et al [59] further call for urgent curricular reform to prepare nurses for AI-enabled health care. Embedding AI into nursing education can demystify the technology, highlight its clinical benefits, and provide hands-on experience that builds confidence and competence.

At a policy level, priorities should include establishing clear interoperability standards, developing robust ethical guidance, and ensuring ongoing professional development for AI use in nursing. At a practice level, health care organizations should actively involve nurses in the design, testing, and evaluation of AI tools to ensure they meet usability and clinical relevance standards. Structured training programs can reduce resistance, improve confidence, and normalize AI use before nurses enter practice, which could help to translate positive perceptions into long-term adoption in real-world clinical settings.

Nursing Research

The findings of this review highlight several key areas for future nursing research. First, there is a need for studies exploring the optimal integration of AI systems into nursing workflows, focusing on usability, interoperability, and the impact on patient care outcomes. Research should investigate how AI can supplement clinical decision-making without replacing nursing judgment, which may go some way to addressing concerns about overreliance on technology. Second, given the critical role of education in fostering AI adoption, studies should examine effective strategies for incorporating AI education into nursing curricula and continuing professional development. This includes exploring the use of innovative educational tools to prepare nurses for the evolving health care landscape. Third, research is needed on the long-term effects of AI integration on nursing roles, job satisfaction, and patient-nurse relationships. Finally, studies should address the ethical implications of AI in nursing, including issues of data privacy, algorithmic bias, and the potential transformation of nursing practice. By focusing on these areas, future research can guide the development of AI technologies that enhance nursing practice while preserving the core values of compassionate, patient-centered care.

Limitations

A key strength of this review is its comprehensive synthesis across diverse AI applications and settings, supported by a transparent search strategy and appraisal process using the MMAT [22]. Another strength is the structured use of the TAM2

XSL•FO
RenderX

framework [16], which provided a consistent lens for analysis and allowed for thematic comparison across studies, although, as noted below, this carries trade-offs for inductive emergence.

There are 6 notable limitations. First, the included studies encompassed a heterogeneous range of AI technologies and contexts, from sepsis prediction tools to natural language processing documentation aids, which limits the generalizability of specific implementation recommendations. In particular, conclusions regarding workflow alignment and facilitating conditions are likely to be highly context-dependent and should not be applied uniformly across all AI tool types or care settings.

Second, many studies involved multidisciplinary participant samples in which nurses were not always the majority, and in several cases, nursing data were aggregated with data from other professions. Where studies included multidisciplinary samples, nurse-specific data were extracted separately where the primary data permitted, as documented in Multimedia Appendix 2. In a small number of studies where profession-specific disaggregation was not possible, findings may reflect broader health care professional perspectives rather than distinctly nursing experiences, and these cases are flagged explicitly in Multimedia Appendix 2.

Third, the deductive analytical framework carries an inherent trade-off. TAM2 was selected a priori and registered with PROSPERO, which ensures transparency and reduces post hoc analytical drift; however, coding line-by-line into prespecified constructs may have constrained the emergence of nursing-specific themes that did not map cleanly onto these categories. We did not encounter substantial extracts that fell entirely outside the framework, although themes relating to professional identity, relational care, or moral distress may be more likely to be visible under inductive analysis. Dimensions such as professional identity, relational care, ethical responsibility, and moral distress in AI-assisted practice may therefore be underrepresented in the synthesis not because they were absent from the primary literature, but because the framework did not create space for them. Inductive or hybrid reanalysis of this literature could potentially surface a complementary picture and is recommended as a priority for future qualitative synthesis.

Fourth, coding of the included studies was undertaken by a single reviewer (AJSS), with regular consultation and consensus discussion of coding decisions with 2 supervising coauthors (BCB and DD) but without independent double-coding of the data. While the consultative process was designed to support consistent application of the codebook, the absence of independent dual coding means that formal interrater agreement could not be calculated, and we cannot fully exclude the possibility of single-coder interpretative bias. This limitation is partially mitigated by the use of a transparent, preregistered framework and by the iterative supervisory review process, but readers should weigh the synthesis findings with this constraint in mind.

Fifth, although the search syntax was not restricted by language, inclusion criteria were limited to studies published in English. This decision was made on practical grounds of interpretive validity, but we acknowledge that it may have excluded relevant empirical work from non-English speaking health care contexts, which could have captured different cultural and organizational dimensions of nurses' AI experiences.

Finally, the rapid pace of AI development means that nurses' perceptions are likely to evolve over time, potentially affecting the long-term applicability of these findings.

Conclusions

This systematic review synthesizes nurses' experiences with AI in clinical practice, identifying both the opportunities and challenges associated with its integration. While nurses often view AI as a means to enhance workflows, support decision-making, and contribute to patient care, adoption is reported to be hindered by barriers such as usability issues, limited training, and concerns about trust and clinical relevance. It is important to note that this review captures nurses' reported perceptions and experiences, rather than direct evidence that AI improves patient outcomes, workflow efficiency, or clinical safety; such claims require prospective evaluation. Addressing these challenges requires aligning AI development with user needs and embedding robust education and training into both preregistration curricula and continuing professional development. The consistent findings that facilitating conditions are the primary determinant of positive experience suggest potential value in involving nurses meaningfully in the co-design and iterative refinement of AI tools; this inference is drawn from the weight of evidence on implementation prerequisites rather than direct evidence on participatory design processes, which were only sparsely reported in the included literature. Prospective evaluation using nursing-relevant outcomes, including usability, workflow integration, and trust calibration, is needed to establish which specific implementation conditions reliably produce benefit, and to test whether co-design approaches improve adoption in practice.

By closing these gaps, nursing can play a central role in shaping AI tools that enhance, rather than erode, the human elements of care. As AI capabilities evolve, the profession has an opportunity, and a responsibility, to lead their ethical, effective, and patient-centered implementation.

Abstract

Background: Nursing Development Units (NDUs) are structured clinical environments designed to enhance professional development, collaboration, and organizational learning. While NDUs have been widely studied for their impact on nursing practice, their role in supporting digital transformation in health care has been less explicitly examined.

Objective: This scoping review aimed to map the characteristics, structures, and processes of NDUs and identify how these elements may relate to digital readiness and the integration of digital tools in nursing practice.

Methods: We conducted a scoping review of 40 publications describing NDUs. Data were coded iteratively to identify patterns at the individual, interpersonal, and organizational levels. Core elements and subcategories of NDUs were mapped, highlighting potential connections to capacities required for digital transformation.

Results: NDUs operate across three levels: (1) individual—fostering professional role development, leadership, and resilience; (2) interpersonal—promoting participatory cultures, collaborative practice, and shared unit visions; and (3) organizational—providing structured frameworks for practice philosophy, role development, resource and change management, and embedded evaluation systems. While most primary publications did not explicitly address digital competencies, the structures, reflective practices, and collaborative processes described represent foundational capacities for engaging with digital tools, innovation, and organizational change.

Conclusions: NDUs are characterized by multilevel structures and processes that enhance professional and organizational capacities. Although explicit evidence on digital transformation is limited, these capacities align with key prerequisites for the adoption and effective use of digital technologies in nursing practice. Further research is needed to examine how NDUs directly support digital innovation in clinical settings.

nursing development unit; professional development; innovation in nursing; reflective practice; digital transformation; interdisciplinary collaboration; organizational learning; PRISMA

Introduction

Digital transformation is no longer a future scenario in health care but a present reality driven by artificial intelligence, remote monitoring, electronic health records, and data-informed decision-making [1-4]. While these innovations promise improved care quality, efficiency, and patient engagement, their implementation in nursing faces persistent challenges, including digital burnout, workflow disruption, resistance to change, and insufficient staff-centered design [5,6]. These barriers are not merely technical but rooted in organizational culture, leadership, and professional identity. Consequently, digital transformation in nursing often fails due to misalignment between technological innovations and clinical practice [6]. In this review, digital transformation in nursing is understood as a sociotechnical process. It involves technological adoption, changes in professional roles and competencies, and the adaptation of organizational routines and culture.

Nursing Development Units (NDUs) have emerged as a promising model to foster innovation and support digital

XSL•FO
RenderX

transformation in nursing. NDUs are nursing-led, practice-based innovation hubs designed to integrate research, education, and clinical practice through reflective, participatory, and evidence-informed development cycles [7-9]. Unlike isolated pilot projects, NDUs are embedded within health care organizations and supported by dedicated leadership, resources, and evaluation systems, enabling long-term iterative learning and continuous improvement [10,11]. Their core mechanisms—structured reflection, participatory decision-making, and embedded evaluation—directly address known barriers to digital transformation by empowering nurses as cocreators of practice change.

Despite this potential, NDUs remain undertheorized in the context of digital health. Systematic mapping of their conceptual features, functional roles, and organizational frameworks—particularly regarding how they enable or constrain digital transformation—is lacking. Moreover, terminological variation (eg, "Clinical Development Unit," "Practice Development Unit," and "Nursing Professional Unit") complicates cross-contextual comparisons and limits the transferability of insights [11-13]. This conceptual and methodological heterogeneity highlights a key research gap: the absence of a coherent, internationally applicable framework to understand how NDUs function as catalysts for digital innovation in nursing.

This scoping review aimed to address this gap by systematically mapping the international literature on NDUs, synthesizing their core conceptual features, functional roles, and organizational frameworks. The review also explored how NDUs engage with digital transformation—not as passive recipients of technology but as active spaces of knowledge translation [14], organizational change [15], and co-design [16]. A scoping review methodology was chosen due to the conceptual complexity, terminological diffusion, and limited existing synthesis of the NDU concept [17,18]. This approach allows for a comprehensive, transparent, and structured mapping of the literature, providing a foundation for future implementation models and strategies for digital innovation in nursing.

Methods

This scoping review followed the Joanna Briggs Institute methodology [17] and the framework by Arksey and O'Malley [18], which encompasses 4 phases: identifying relevant publications, selecting publications, extracting data, and synthesizing findings. Reporting adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist to ensure transparency and reproducibility [19].

Search Strategy

A systematic literature search was conducted in May 2025 in the databases MEDLINE (via PubMed), ScienceDirect, EBSCO, Cochrane Library, and Europe PMC. Supplementary searches in Google Scholar and LIVIVO captured gray literature and publications not indexed in biomedical databases. Results were sorted by relevance, and all retrieved records were screened without a stopping rule to maximize sensitivity.

The primary database search used the exact phrase "Nursing Development Unit" to prioritize conceptual precision. No additional filters (eg, publication year, study design, or language) were applied to capture the complete literature on NDUs. This decision was grounded in the historically established use of the term. In the literature, "NDU" often denotes a defined organizational model rather than a generic practice development activity. We anticipated that broader search strings (eg, including "Practice Development Unit" or "Clinical Development Unit") would markedly increase retrieval in the main databases. Much of this literature is conceptually adjacent but heterogeneous (eg, general practice development, quality improvement, or clinical education units) and does not necessarily reflect the NDU model targeted in this review.

To reduce the risk of missing relevant publications due to terminological variation, we complemented the core database search with supplementary searches and screened for records that provided structural or process descriptions consistent with NDUs (eg, "Clinical Development Unit," "Practice Development Unit," "Nursing Clinical Development Unit," and "Nursing Professorial Unit"). The full MEDLINE search syntax is provided in Multimedia Appendix 1.

Publications were included if they described structural, functional, or organizational characteristics of NDUs, as well as development processes and implementation strategies. Publications primarily evaluating effectiveness or outcomes (eg, patient metrics and clinical performance) were excluded as the focus was on conceptual mapping rather than outcome assessment. Disease- or population-specific NDUs were included only if they provided insights into NDU structures or processes. Only English- or German-language publications with available full texts were considered. English was used to ensure coverage of the international literature, whereas German-language publications were included for feasibility given the review team's proficiency. Textbox 1 summarizes the eligibility criteria.

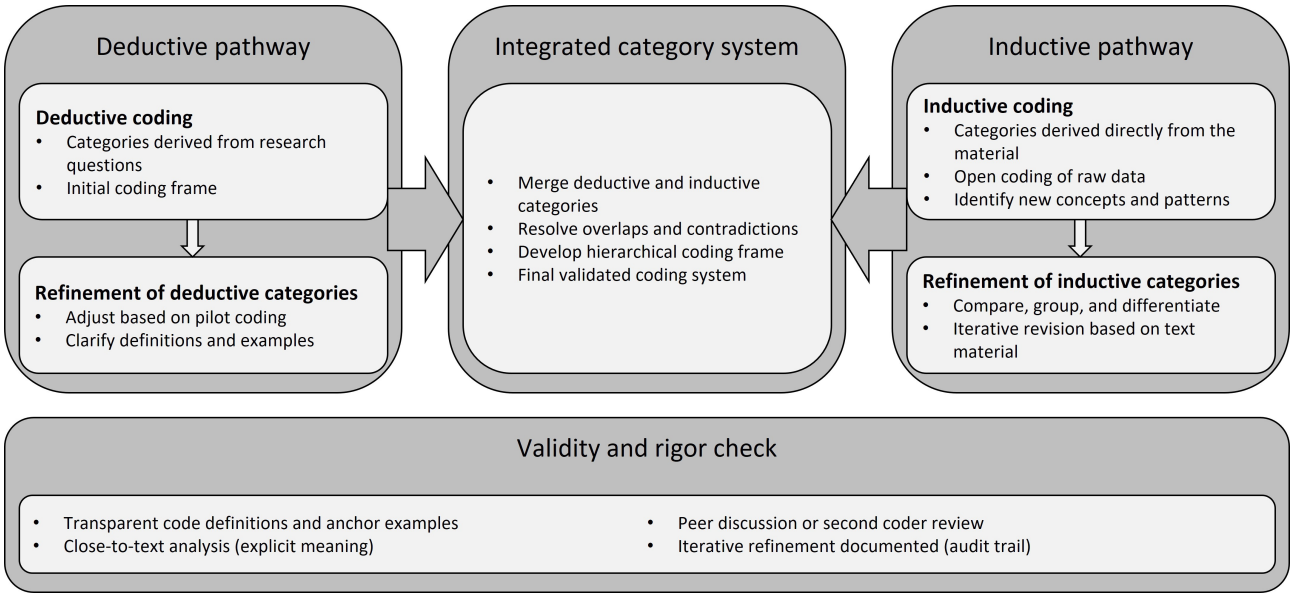
Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Empirical and conceptual publications with abstracts available
- Language: German or English
- Description of content-related aspects, progressive development process, and implementation strategies of Nursing Development Units (NDUs)

Exclusion criteria

- Disease-specific focus (unless NDU structures or processes were described)
- Evaluation of NDUs (effectiveness or outcomes)
- Full text not available



Publication Selection and Data Extraction

Duplicate records were manually removed based on title, author, digital object identifier, journal, and year. Three reviewers (AG, PM, and KG) independently screened titles and abstracts, and any record deemed eligible by at least one reviewer progressed to full-text review. The involvement of 3 reviewers at this stage was chosen to efficiently manage the large number of retrieved records.

Full-text screening was performed independently by 2 reviewers (AG and KG) using predefined inclusion and exclusion criteria, with disagreements resolved through discussion. All included publications were full-text documents (peer-reviewed articles or gray literature reports) that underwent thematic analysis. Data extraction followed a standardized charting framework capturing structural, functional, and organizational characteristics; development and implementation processes; and references to digital transformation where present. Each publication was extracted by a single reviewer, with the framework ensuring consistency. Given the more in-depth nature of full-text assessment, the involvement of 2 reviewers was considered sufficient to ensure consistency and methodological rigor.

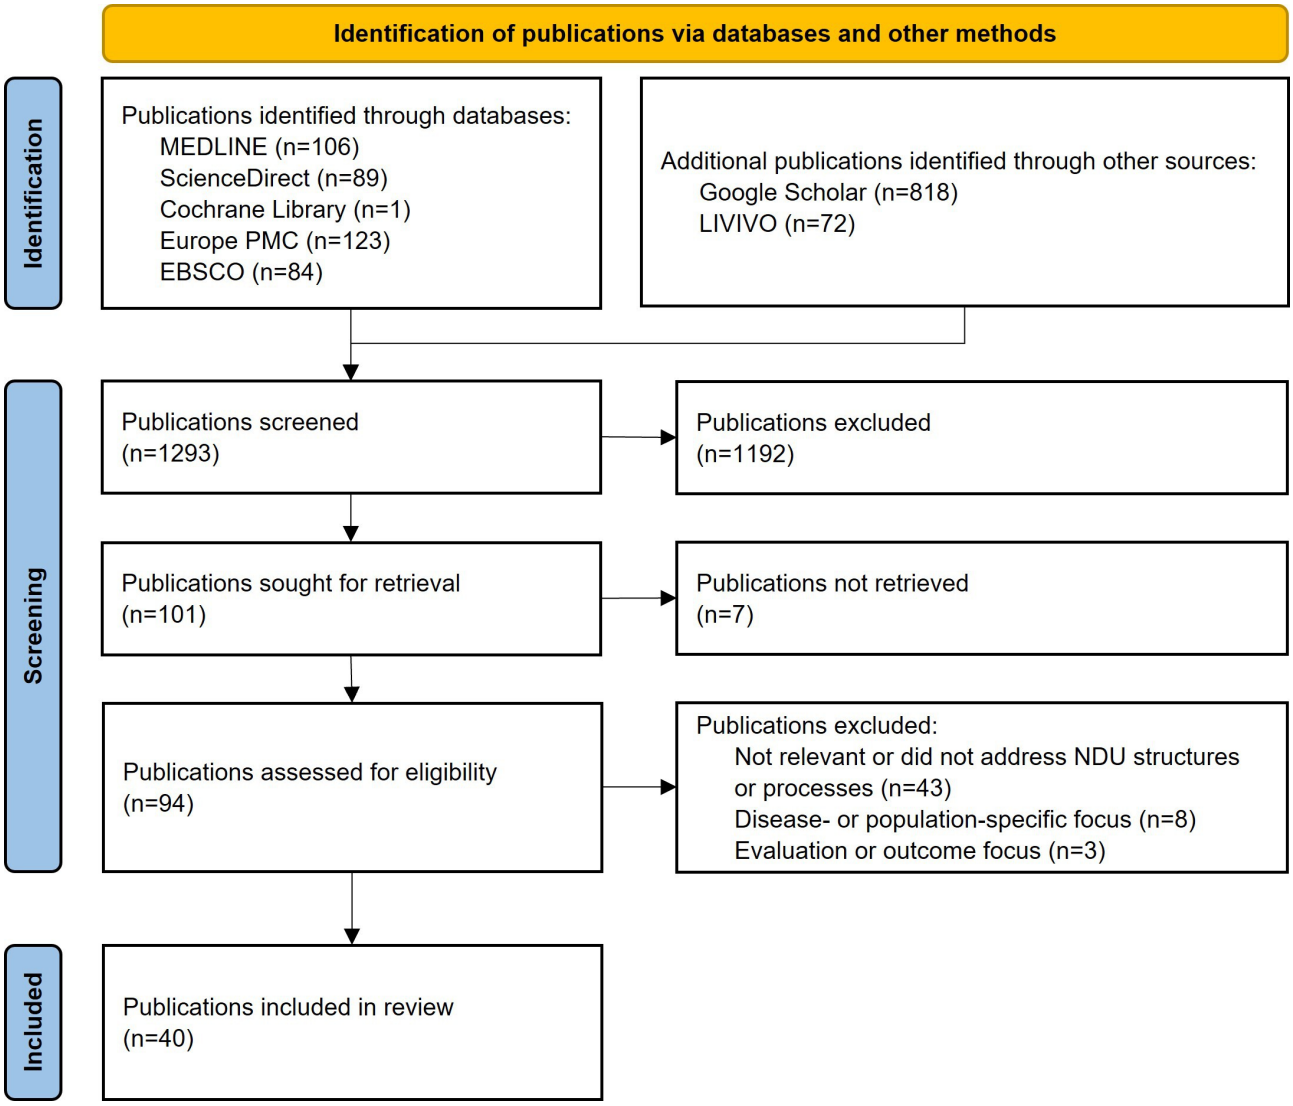
A qualitative synthesis was conducted using the structured qualitative content analysis by Kuckartz and Rädiker [20], as recommended by Levac et al [21]. Thematic categories emerged through an iterative process: (1) deductive mapping of initial categories from the research questions (eg, “leadership identity”), (2) inductive coding of all publications to identify recurring patterns, and (3) aggregation of overlapping patterns into the final thematic structure through team consensus. Category definitions, anchor examples, and iterative coding refinement ensured analytical rigor. Figure 1 [20] illustrates the process.

Figure 1. Qualitative content analysis process according to Kuckartz and Rädiker [20] (applied in this review).

Ethical Considerations

As this study was a scoping review of published literature, it did not involve human participants, and therefore, ethics approval was not required.

Results



Publication Selection

The database search conducted in May 2025 yielded 1293 records: 106 (8.2%) from MEDLINE (via PubMed), 818 (63.3%) from Google Scholar, 72 (5.6%) from LIVIVO, 89

XSL•FO
RenderX

(6.9%) from ScienceDirect, 1 (0.1%) from the Cochrane Library, 123 (9.5%) from Europe PMC, and 84 (6.5%) from EBSCO. After removing duplicates and screening titles and abstracts, of the 1293 publications, 101 (7.8%) underwent full-text review. Applying the predefined eligibility criteria resulted in 40 publications included for in-depth analysis. No unresolved disagreements occurred during the selection process. The publication selection process is illustrated in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart (Figure 2 [22]).

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart illustrating the study selection process (adapted from Moher et al [22]). NDU: Nursing Development Unit.

Main Characteristics of the Included Publications

The 40 included publications originated from the United Kingdom (n=26, 65%) and Australia (n=14, 35%) and covered the period from 1991 to 2017. Most publications were in English (n=39, 97.5%), with 2.5% (n=1) in German. Study designs comprised qualitative, quantitative, mixed methods, and conceptual approaches. The publications examined how professional roles, leadership, collaborative practices, organizational structures, and reflective processes shape nursing practice. Publication characteristics are summarized in Table 1.

XSL•FO
RenderX

Table . Characteristics of the included publications (N=40).

Study	Country	Design	Focus	Purpose
Atsalos and Greenwood [8], 2001	Australia	Qualitative	Leadership experiences in NDUs[a]	To explore leadership experiences of nurses working in NDUs under conditions of organizational stress

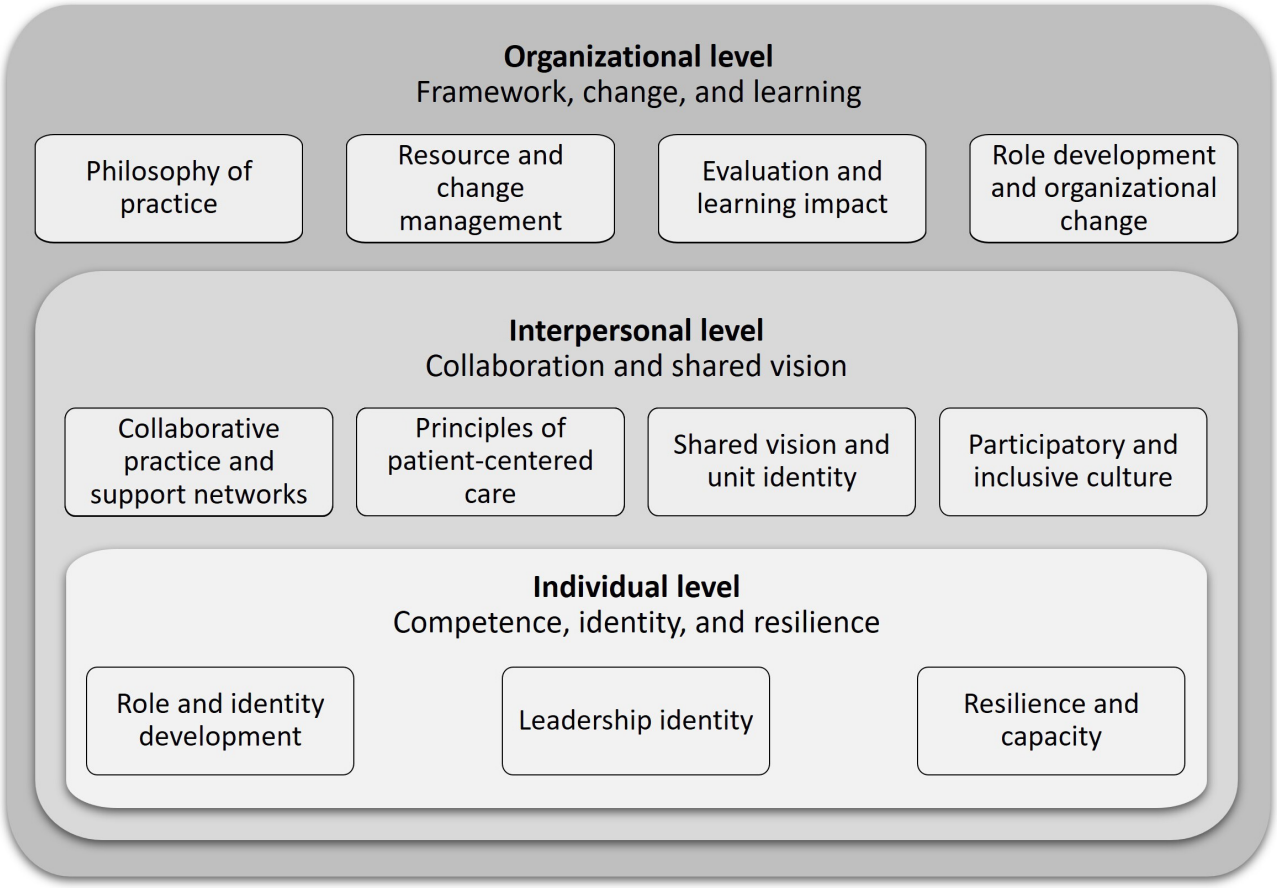
[a]NDU: Nursing Development Unit.

Core Elements of NDUs



Overview

The literature consistently described NDUs as operating across 3 interrelated levels: individual, interpersonal, and organizational (Figure 3). These levels structure descriptions of professional development, collaboration, and organizational learning. This framework emerged inductively from the data through iterative coding of all included publications, reflecting patterns observed in the literature rather than a pre-established theoretical model.

Several characteristics identified at these levels—such as competence development, participatory practices, and embedded learning structures—are discussed in the broader literature on organizational readiness for change and digital transformation. While explicit engagement with digital technologies was seldom reported in the included publications, the identified capacities and practices indicated potential enablers for adopting digital tools and supporting digital innovation in nursing.

XSL•FO
RenderX

Figure 3. Core elements of a Nursing Development Unit inductively synthesized from the included publications.

Individual Level: Competence, Identity, and Resilience

NDUs were described as settings in which professional roles, leadership capabilities, and personal resilience are addressed. Activities included reflective practice, integration of ethical and evidence-based principles, and adaptation to evolving clinical demands. Table 2 maps publications contributing to individual-level components.

A clear understanding of professional roles, the integration of personal and shared philosophies of practice, and the development of self-efficacy and professional coherence were described as central elements of role and identity development [23,43]. Several publications highlighted intrinsic motivation and self-awareness in relation to personal growth and competence development [23].

Table . Mapping publications to individual-level components of Nursing Development Units (n=17).

Level and subcategory	Publications
Individual	
Role and identity development	[8,10,23,25,33-35,43,45,47,54]
Leadership identity	[8,23,26,29,31,35,39]
Resilience and capacity	[27,34,44,45,54]

Reflective practice was described as integrating ethical considerations, clinical judgment, and personal values into everyday care [43]. The literature reported structured forms of reflection, including written protocols, workshops, and reflective models, which were used to support critical inquiry into values, roles, and routines and articulate emerging professional identities within NDUs [33,34]. Modular training programs addressing clinical and research competencies were described across several publications and commonly linked to supervision and assessment processes [10].

Leadership identity was addressed in a subset of publications (7/17, 41.2%), which described clinical leaders as taking on facilitative and innovative roles and as supporting team processes. At the same time, challenges such as variable staff motivation and uncertainty regarding the NDU concept were reported [8,23]. Leadership support structures, including mentorship, networking, and formal development programs, were described in relation to team support during periods of change [31].

Several publications (5/17, 29.4%) described NDUs as contexts in which professional resilience is addressed, particularly in relation to iterative development processes and challenges associated with time constraints, emotional labor, and organizational obstacles [23,43]. Staff perceptions reported in

XSL•FO
RenderX

the literature included high expectations, impatience for visible progress, and difficulties adjusting to evolving roles [43].

Across the included publications, reflective practice, continuous competence development, and leadership identity were recurrently described at the individual level. While the reviewed publications did not explicitly address digital competencies or digital practices, they outlined professional capacities—such as critical reflection, adaptability, and role clarity—that are frequently discussed in the broader literature in relation to organizational and technological change.

Interpersonal Level: Collaboration and Shared Vision

Across the included publications, NDUs were described as fostering participatory and inclusive cultures, supporting collaborative practices, and facilitating the development of shared visions and unit identities. Several publications reported that team interactions and decision-making processes emphasized principles of patient-centered care. Table 3 summarizes the publications contributing to the interpersonal-level subcategories.

Participatory and inclusive cultures were described as involving collaboration, shared decision-making, and ongoing improvement [32,53]. Publications reported that traditional nursing boundaries were sometimes transcended, enabling staff to engage in collective reflection, articulate unit philosophies, formulate action plans, and evaluate progress. Bottom-up approaches, including staff participation as coresearchers, were described in relation to collective ownership of practice change [32,45].

Table . Mapping publications to interpersonal-level components of Nursing Development Units (n=30).

Level and subcategory	Publications
Interpersonal	
Participatory and inclusive culture	[8,23-25,32,34,40,42,43,53,54]
Collaborative practice and support networks	[24,25,34,37,39,41,45,47,50,52,53]
Shared vision and unit identity	[9,11-13,28,33,36-38,40,42,44,46,49]
Principles of patient-centered care	[8,27,38,43,44,52,53]

Collaborative practices and support networks were described as developing through mentorship and interdisciplinary teamwork, supporting staff in addressing challenges and continuing professional growth [23,49]. Strategic planning processes were reported to clarify team needs, anticipate obstacles, and link practice activities to evidence generation. Several publications described collaborative planning as fostering shared ownership and a collective vision for change [54]. Partnerships with academic institutions were reported to support training, research, and innovation [9,49].

Shared vision and unit identity were described as contributing to team coherence. Staff involvement in defining the NDU's purpose, intended outcomes, and guiding principles was frequently reported [43,45,54]. The literature highlighted that shared philosophies of practice grounded in clinical realities and staff perspectives can reinforce team coherence and collective identity [43]. Exposure to experiences from other NDUs was reported to help manage expectations, facilitate collective problem-solving, and support ongoing development [44].

Patient-centered care was described as emphasizing trust, sensitivity, shared decision-making, and patient autonomy [8,43]. Evidence-based approaches were reported across NDUs, although implementation varied. Some publications reported extensive evaluation frameworks, whereas others focused on routine questioning and evidence-informed decisions [9]. Integration with relational care models such as primary nursing was described as an example of applying patient-centered principles in practice [8,43,53].

Across the reviewed publications, participatory cultures, collaborative planning, and shared decision-making were consistently reported as central interpersonal characteristics of NDUs. Although digital technologies were not explicitly addressed, these interactional patterns reflected approaches commonly discussed in the broader literature for co-designing and implementing complex interventions, including digital tools in health care settings.

Organizational Level: Framework, Change, and Learning

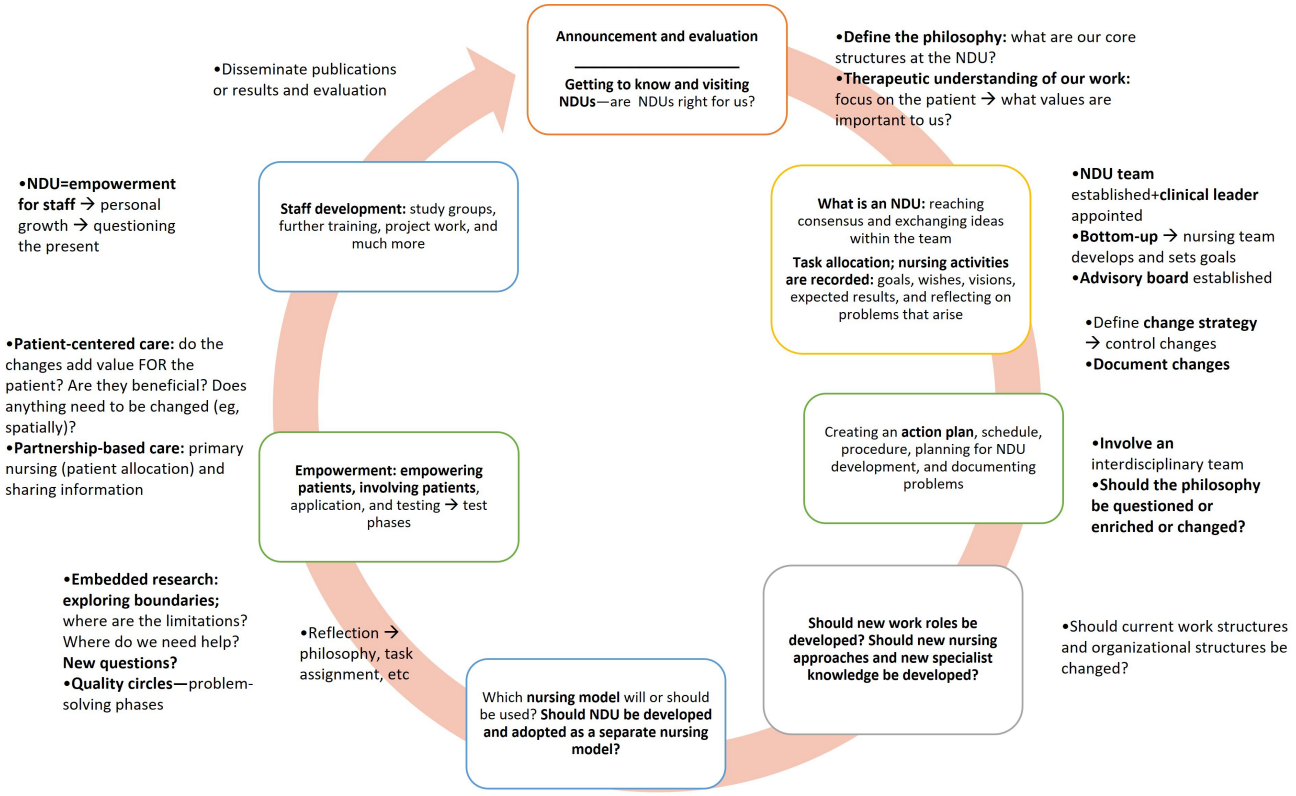
At the organizational level, NDUs were described as involving frameworks and structures that support practice development, change, and learning. Several publications highlighted overarching philosophies of practice, structured role development, and embedded evaluation systems as recurring elements. Table 4 summarizes the publications contributing to the organizational-level subcategories.

XSL•FO
RenderX

Table . Mapping publications to organizational-level components of Nursing Development Units (n=31).

Level and subcategory	Publications
Organizational	
Philosophy of practice	[7,9,11-13,28,33,35-38,40-44,46,48-51,55]
Resource and change management	[9,12,13,26,31,32,36-39,41,44,46,48,49,51,55]
Role development and organizational change	[10,11,29,33,35,37,43,47,51]
Evaluation and learning impact	[7,28,30-32,39,41,48,50-53,55]

Philosophies of practice were described as providing frameworks of values, guiding principles, and standards that inform unit culture and practice [51]. Role development and organizational change were reported in relation to clarifying responsibilities, establishing decision-making processes, and supporting structural adjustments to avoid duplication and facilitate innovation [33,53].



Management of resources and change was described in the literature as including strategies to allocate time and materials, address resistance, and respond to operational pressures [49,53]. Evaluation and learning systems were reported to support reflective processes, facilitate improvements based on evidence, and connect practice to research and learning across disciplines [50,51,53]. Iterative development processes using structured strategies, participatory approaches, and strategic planning were described as approaches to respond to local needs while maintaining growth and improvement [10,11,29,50,51,53,54].

Embedded evaluation systems and iterative learning cycles were frequently reported as integral to NDU development. While these publications did not specifically address digital innovations, the described organizational infrastructures and learning mechanisms were consistent with approaches that are widely considered relevant for implementing and adapting complex interventions, including digital tools in health care settings.

Development and Implementation Process of NDUs

NDU development was reported as a multiyear, iterative process involving alignment of organizational structures, professional identity formation, and collaborative teamwork (Figure 4). Implementation evolves through cycles of reflection, strategic planning, practice-based experimentation, and evidence-informed evaluation grounded in a shared philosophy of practice that incorporates diverse staff perspectives and emphasizes holistic, patient-centered nursing [8,11,43,55].

Figure 4. Progressive development toward a Nursing Development Unit (NDU) synthesized inductively from the included publications.

Implementation practices reported included client-centered care, nurse empowerment, and evidence-based routines [11,29]. Adaptations to local cultural, staffing, and regional conditions were described as supporting flexibility while maintaining core principles [49]. Staff engagement in data collection and analysis was reported to facilitate learning, support innovation uptake, and foster interdisciplinary thinking [50,51,53].

XSL•FO
RenderX

Challenges reported in the literature included staff turnover, limited acceptance by other health care professionals, high workloads, and gaps between theory and practice. Sustained leadership support and team commitment were described as important factors for maintaining NDU development over time [28].

Discussion

Core Characteristics of NDUs: A Foundation for Innovation

This scoping review mapped the structural and procedural characteristics of NDUs across individual, interpersonal, and organizational levels based on 40 international publications from the United Kingdom and Australia spanning 1991 to 2017. The findings confirm NDUs as multilevel, practice-based innovation spaces that foster professional development, collaborative cultures, and structured learning. These characteristics are not merely descriptive but reflect a coherent framework for supporting continuous improvement and evidence-informed practice.

At the individual level, NDUs are not merely settings for skill development but spaces for professional identity formation. The emphasis on reflective practice, leadership identity, and resilience suggests that NDUs support nurses in navigating complex clinical realities and evolving roles [10,23,33,43]. This process fosters psychological safety and self-efficacy—conditions that are increasingly recognized as essential for adaptive learning and innovation [56,57].

At the interpersonal level, NDUs function as cocreation platforms. The documented practices of shared decision-making, collaborative planning, and peer learning indicate a culture where knowledge is coproduced rather than imposed in a top-down manner [23,32,45,50]. This participatory orientation aligns with contemporary models of human-centered design and may reduce resistance to change—especially when introducing new technologies [16,58].

At the organizational level, NDUs are defined by structured learning cycles and embedded evaluation systems. Their iterative development process—rooted in reflection, experimentation, and feedback—mirrors established frameworks for organizational change [10,11,29,50,51,53]. This suggests that NDUs are not static entities but dynamic systems capable of continuous adaptation, a quality that is critical in rapidly evolving digital health environments [59,60].

Crucially, these characteristics are not isolated features but interconnected processes that reinforce one another. For example, individual reflection is amplified through team dialogue, team collaboration is guided by organizational frameworks, and organizational learning is sustained through individual and team engagement. This synergistic interplay positions NDUs as potential organizational incubators for innovation—although the extent to which they support digital transformation remains to be empirically tested.

Implications for Digital Transformation: A Cautious Interpretive Framework

While the included publications did not explicitly address digital technologies, the identified characteristics of NDUs suggest potential conditions that may support digital transformation in nursing. This section presents these connections as interpretive transfer hypotheses—plausible inferences based on conceptual alignment with known prerequisites for successful technology adoption.

NDUs may support digital transformation by fostering the professional and organizational capacities required for technology integration. For instance, reflective practice and continuous competence development—core to NDUs—can help nurses critically engage with digital tools, align them with ethical and clinical values, and integrate them meaningfully into care routines [33,34,43]. This supports the development of a digital professional identity where technology use is not seen as an external imposition but as an extension of nursing expertise [5,6,61,62].

The participatory culture of NDUs—characterized by shared decision-making, co-design, and peer learning—may reduce resistance to change and improve the fit of digital tools with clinical workflows [16,63-65]. By involving nurses in the design, testing, and evaluation of digital solutions, NDUs could serve as safe spaces for experimentation, where failures are reframed as learning opportunities [15,16]. This aligns with human-centered design principles and may enhance user acceptance and long-term sustainability [58].

At the organizational level, the structured frameworks for change management, iterative evaluation, and evidence-based practice in NDUs mirror the adaptive and learning-oriented processes needed for digital implementation [7,15,50,51]. The emphasis on feedback loops, strategic planning, and continuous improvement provides a robust infrastructure for managing the uncertainties and disruptions associated with digital innovation [60,66].

However, these implications must be interpreted with caution. The evidence base is limited in both temporal and technological scope: most included studies (39/40, 97.5%) were published before 2007, and none explicitly examined digital tools or competencies. Therefore, the claim that NDUs "support digital transformation" should not be understood as a proven causal relationship but rather as a plausible hypothesis that requires empirical validation in contemporary digital contexts.

Strengths and Limitations

This review's strength lies in its systematic and transparent approach guided by established frameworks (Joanna Briggs Institute and PRISMA-ScR guidelines). The inclusion of diverse study types and international literature provides a broad understanding of NDU development and implementation. The independent screening and iterative data extraction process enhances rigor, transparency, and generalizability.

Several limitations must be acknowledged. First, while this review focused on publications explicitly labeled as "Nursing Development Unit," it is possible that related concepts or

XSL•FO
RenderX

alternative labels (eg, “Clinical Development Unit” and “Practice Development Unit”) exist in more recent (digital) nursing literature and may share similar mechanisms for supporting innovation and technology adoption. Although supplementary searches were conducted, our decision to anchor the database search to the exact phrase “Nursing Development Unit” may have led to missed publications describing comparable models under different terminology. Consequently, our synthesis should be interpreted as mapping the literature that explicitly self-identified as “NDU” rather than exhaustively capturing all international Practice Development Unit models. Second, the age of the included publications (mostly published before 2007) limits the direct applicability of the findings to current digital health landscapes, where technologies such as artificial intelligence, real-time monitoring, and interoperable electronic health records are increasingly central. Third, the lack of outcome evaluations and the heterogeneity of definitions and implementation contexts reduce the comparability of the findings. Fourth, the exclusion of non–English- and non–German-language publications may have introduced language bias. Fifth, the absence of a formal quality appraisal—typical in scoping reviews that prioritize conceptual mapping over effect estimation—limits the comprehensive assessment of the robustness of individual findings.

These limitations underscore the need for future research to explicitly link NDU principles with digital transformation using contemporary case studies, mixed methods designs, and outcome-focused evaluations.

Conclusions: A Foundation for Future Inquiry

This review demonstrates that NDUs are structured environments that promote professionalization, collaboration, and learning through multilevel processes. While the evidence base does not directly support claims about digital transformation, the core characteristics of NDUs—reflective practice, participatory cultures, and iterative learning—may offer enabling conditions for the adoption and integration of digital technologies in nursing.

However, these connections remain theoretical and require empirical testing. Future research should investigate how NDUs can be adapted to support digital innovation, with a focus on digital competencies, workflow integration, ethical considerations, and staff well-being. Only through such research can we determine whether NDUs are indeed a viable foundation for digital transformation in nursing or whether new models are needed to meet the demands of the digital age.

Funding

This research was funded by the Federal Ministry of Research, Technology, and Space (grant ID 01ZZ2401A). The study has been funded for a 5-year period starting in November 2024. The study was funded for €4,559,301.88 (US $5,291,298). The funder had no involvement in the study design; data collection, analysis, and interpretation; or writing of the manuscript. The authors acknowledge the financial support of the Open Access Publication Fund of Martin Luther University Halle-Wittenberg.

Abstract

Background: Patient safety is a fundamental pillar of health care quality. Simulation-based training provides a controlled environment for nursing students to develop safety competencies and error-recognition skills before clinical practice.

Objective: This systematic review aimed to describe and characterize the simulation-based education features and modalities used to address patient safety outcomes in undergraduate nursing students, identifying the strategies that contribute to improvements in safety-related competencies.

Methods: A systematic review was conducted following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines across PubMed, Web of Science, Scopus, CINAHL, Cochrane, and Lilacs (2019 - 2024). Inclusion criteria focused on original studies involving undergraduate nursing students and simulation interventions measuring patient safety outcomes. Studies in languages other than English, Spanish, or Portuguese were excluded. Two reviewers independently performed study selection and data extraction. Methodological quality was assessed using Joanna Briggs Institute tools, applying a 60% quality threshold for inclusion. Results were synthesized through a narrative approach.

Results: A total of 20 studies from 12 countries were included. The methodological quality was high (n=14) and moderate (n=6). Findings revealed that high-fidelity simulation and virtual reality are the primary strategies used. Simulation proved effective in enhancing both technical skills (medication administration accuracy) and nontechnical skills (communication via SBAR [Situation, Background, Assessment, Recommendation] and ISBAR [Identification, Situation, Background, Assessment, Recommendation] tools, teamwork, and adverse event reporting). Key strategies contributing to safety included repetitive practice and interprofessional simulation, which significantly improved error detection and clinical judgment.

Conclusions: Simulation is an essential pedagogical strategy for preparing nursing students to deliver safe care. Practical implications include the need to integrate structured simulation into nursing curricula to bridge the theory-practice gap. Future research should prioritize longitudinal designs to assess the retention of these safety skills in clinical settings and develop standardized metrics for measuring patient safety outcomes.

Introduction

Overview

Patient safety is a fundamental pillar of quality health care, aimed at minimizing risks and preventing harm during medical care [1]. According to the World Health Organization (WHO), this concept is defined as "the absence of avoidable harm to a patient and the reduction to an acceptable minimum of the risk of unnecessary harm associated with healthcare" [2]. Despite its importance, safety failures remain a critical global issue; more than 1 in 10 patients suffer harm during treatment, leading to more than 3 million deaths annually. Consequently, unsafe care must be recognized as both a major public health crisis and a significant economic burden [3].

The study of these failures gained international prominence following the landmark report "To Err is Human," published in 2000 by the National Academy of Sciences. This study revealed that the cost of medical errors extends beyond economics, deeply affecting patient satisfaction, professional morale, and overall trust in the health system [4]. To address these challenges, a comprehensive monitoring approach is required. This involves the proactive identification of hazards, continuous process improvement, and the promotion of a safety culture that actively engages both health care professionals and patients [1].

Patient safety culture is a complex phenomenon in which values, attitudes, competencies, and behaviors influence how health care professionals perceive and manage safety risks [2]. A comprehensive framework for patient safety culture consists of leadership, teamwork, evidence-based practice, communication, learning, just culture, and patient-centered care [5]. This concept is integrated with WHO resolution WHA72.6 [6], which prioritizes concrete measures to prevent avoidable harm in health care, such as strategies for safe medication, error-free surgery, infection control, sepsis management, reliable diagnostics, and adequate hygiene in facilities. This multidimensional framework highlights the systemic nature of safety culture and the central role of leadership and communication in preventing adverse events.

The occurrence of safety incidents is rarely the result of a single individual's actions but rather the culmination of various systemic factors [4]. These include rapid technological advances, increasingly complex care processes, inadequate policies, and an aging population with multiple chronic comorbidities [2]. Because incidents often stem from multiple overlapping causes, focusing on individual blame fails to address the underlying systemic issues, making it likely that the same errors will recur [2,4]. To mitigate these risks, the Global Patient Safety Action Plan 2021‐2030 outlines strategic activities designed to identify, evaluate, and manage risks throughout the health care continuum, with the ultimate goal of preventing harm or minimizing its impact [7].

Training and education in safe practices are essential to maintaining and improving standards of care and ensuring that health systems can adapt and respond to emerging challenges in health care [1]. In this context, simulation, defined as any technique that extends or replaces real-world experiences to promote reflective learning, has established itself as a key strategy for improving research on patient safety incidents [8].

Clinical simulation has proven effective as a teaching strategy for developing both technical and nontechnical skills, including communication, teamwork, leadership, and critical thinking [9,10]. This approach allows for the creation of structured, meaningful, and reflective learning environments that facilitate the effective and safe resolution of complex situations, in line with the competencies to be acquired [8-10].

Clinical scenarios form the basis of clinical simulation, as they allow learning experiences to be structured with different levels of complexity in line with training objectives [11]. A key element in their design is fidelity, understood as the degree to which the simulation reproduces the conditions of actual clinical practice [12], which can be classified as low, medium, or high depending on the resources used and the educational goals. Low-fidelity simulation typically focuses on the acquisition of basic technical skills using task trainers, simple manikins, or case studies, while medium and high levels incorporate more complex scenarios and greater realism. Similarly, the simulation modality refers to the format used to develop the training experience. According to the Healthcare Simulation Dictionary, these modalities can include role-playing, virtual or online simulations, task trainers, high-tech mannequins, or immersive simulations with standardized patients (SPs) or trained actors [12]. Thus, the combination of modality and fidelity level allows simulation to be adapted to different educational contexts and clinical competencies [11]. Immersive simulation, particularly when based on realistic clinical scenarios, offers strong opportunities to develop competencies and promote changes in thinking and practice. Its effectiveness is enhanced when followed by structured debriefing, enabling reflective analysis and identification of improvement strategies [9].

Nursing professionals, from their formative stage, need to be actively trained to provide safe care, and effective communication is essential to reduce health errors [13,14]. A culture of open communication facilitates enhanced team interactions and equips students with efficacious strategies to deploy in their practice, thereby fostering critical thinking and emergency management skills. The formation of effective interprofessional teams through simulation-based learning has been linked to improved patient outcomes, a reduction in medical errors, and the delivery of high-quality care [15]. The students have acquired knowledge and have been instructed in the guidelines for conducting practices more safely. However, they encounter obstacles when attempting to communicate and report errors, as they perceive themselves to have a lower status and are sometimes fearful of the potential consequences [16].

A coalition of international scientific societies with expertise in simulation has issued a call for the integration of simulation-based learning into the curricula of undergraduate and postgraduate programs. This initiative is designed to foster a culture of safety [17]. It is also imperative that the simulation be designed in such a way that it does not compromise the psychological and physical integrity of the participants, while also ensuring the safety of the training process [18].

RenderX

Previous reviews on educational interventions in patient safety highlight considerable methodological heterogeneity and limited evidence regarding the specific impact of simulation [19]. One review found that although patient safety competence was frequently assessed, only 2 studies used simulation, and none examined behavioral changes, limiting conclusions about real clinical impact [18]. A published protocol targeting nursing students also considers simulation among various teaching methods, but anticipates substantial variability that may hinder conclusions about its differential effectiveness [20].

Another systematic review reported improvements in knowledge, clinical skills, and confidence through simulation-based learning; however, it included varying fidelity levels and did not specifically address patient safety outcomes, limiting applicability to this domain [21]. Similarly, quantitative syntheses confirm the benefits of simulation but do not analyze its transfer to patient safety in real health care contexts [22]. A comparison between SPs and role-playing showed improvements in communication skills, yet without linking findings to objective patient safety indicators [23]. Finally, an exploratory review associated simulation with greater competence and confidence but did not differentiate between levels of evidence or modalities, limiting the strength of its recommendations [24].

Overall, despite suggested benefits, the literature shows methodological heterogeneity, limited analysis of behavioral outcomes, and insufficient connection to specific patient safety indicators, raising the question of the actual effect of simulation-based learning on patient safety outcomes in nursing students.

Objective

Since 2020, with the closure of in-person training activities and the impossibility of clinical practices, justified by immediate public health needs: preventing the transmission of infections, facilitating social distancing, and responding to government orders, the need for education and training that adapts to the new demands of the health system has become evident [25,26].

The use of simulation methodology in the education of nursing students can be a strategy that improves the application of the theoretical concepts learned and clinical practice, to provide safe and quality care. The objectives of this systematic review were (1) to determine the effect of simulation-based education on patient safety outcomes in nursing students, (2) to identify the aspects related to patient safety that have been the subject of the use of simulation, and (3) to describe and characterize simulation-based education features and modalities used to address patient safety outcomes in undergraduate nursing students.

Methods

Design

A systematic review was carried out during the months of February and March 2024, following the checklist of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [27]. The review followed the PRISMA 2020 guidelines and was designed and presented as a systematic review rather than an exploratory review, to accurately determine the effect of simulation-based education on patient safety outcomes, establishing strict predefined eligibility criteria, quality assessment, and structured synthesis of evidence (Checklist 1).

Search Strategy

A systematic search was carried out from 2019 to 2024 in the databases: PubMed, Web of Science, Scopus, CINAHL, Cochrane, and Lilacs. These databases were selected to ensure broad coverage of biomedical, nursing, educational, and multidisciplinary research, as well as to minimize publication and indexing bias. To guide the search, we started from the PIO (Population, Intervention, Outcomes) question (Table 1).

The terms were adapted to the controlled language of the MeSH (Medical Subject Headings) and Descriptors in Health Sciences, in addition to CINAHL subject headings (Table 2).

Table . Keywords PIO[a].

PIO question	Keywords	MeSH[b]	DeCS[c]
Population	Nursing students	Nursing students	Estudiantes de enfermería
Intervention	Training through simulation techniques	Simulation training	Simulación
Outcomes	Improving patient safety	Patient safety	Seguridad del paciente

[a]PIO: Population, Intervention, Outcomes.

[b]MeSH: Medical Subject Headings.

[c]DeCS: Descriptors in Health Sciences in Spanish.

[a]WoS: Web of Science.

Inclusion and Exclusion Criteria

The inclusion criteria were articles written in English, Spanish, and Portuguese, which were primary studies on the use of simulation in the undergraduate stages of nursing to maintain patient safety, such as communication, teamwork, medication safety, clinical performance linked to safety, without differentiating the type of simulator used. Although initially it was decided to include only nursing students, it was later decided to also include studies involving medical students in the case of communication or teamwork.

Exclusion criteria were considered qualitative studies, reviews, editorials, personal experiences, and those quantitative articles that were not peer reviewed, studies that dealt exclusively with student satisfaction and perception with the simulation methodology, studies in which among the participants there were already graduated professionals, and those in which at least one of the objectives did not deal with safety, studies on the use of simulators that were specific for learning specialized care, studies referring to the design of simulation scenarios or the development of modifications of educational strategies related to simulation.

RenderX

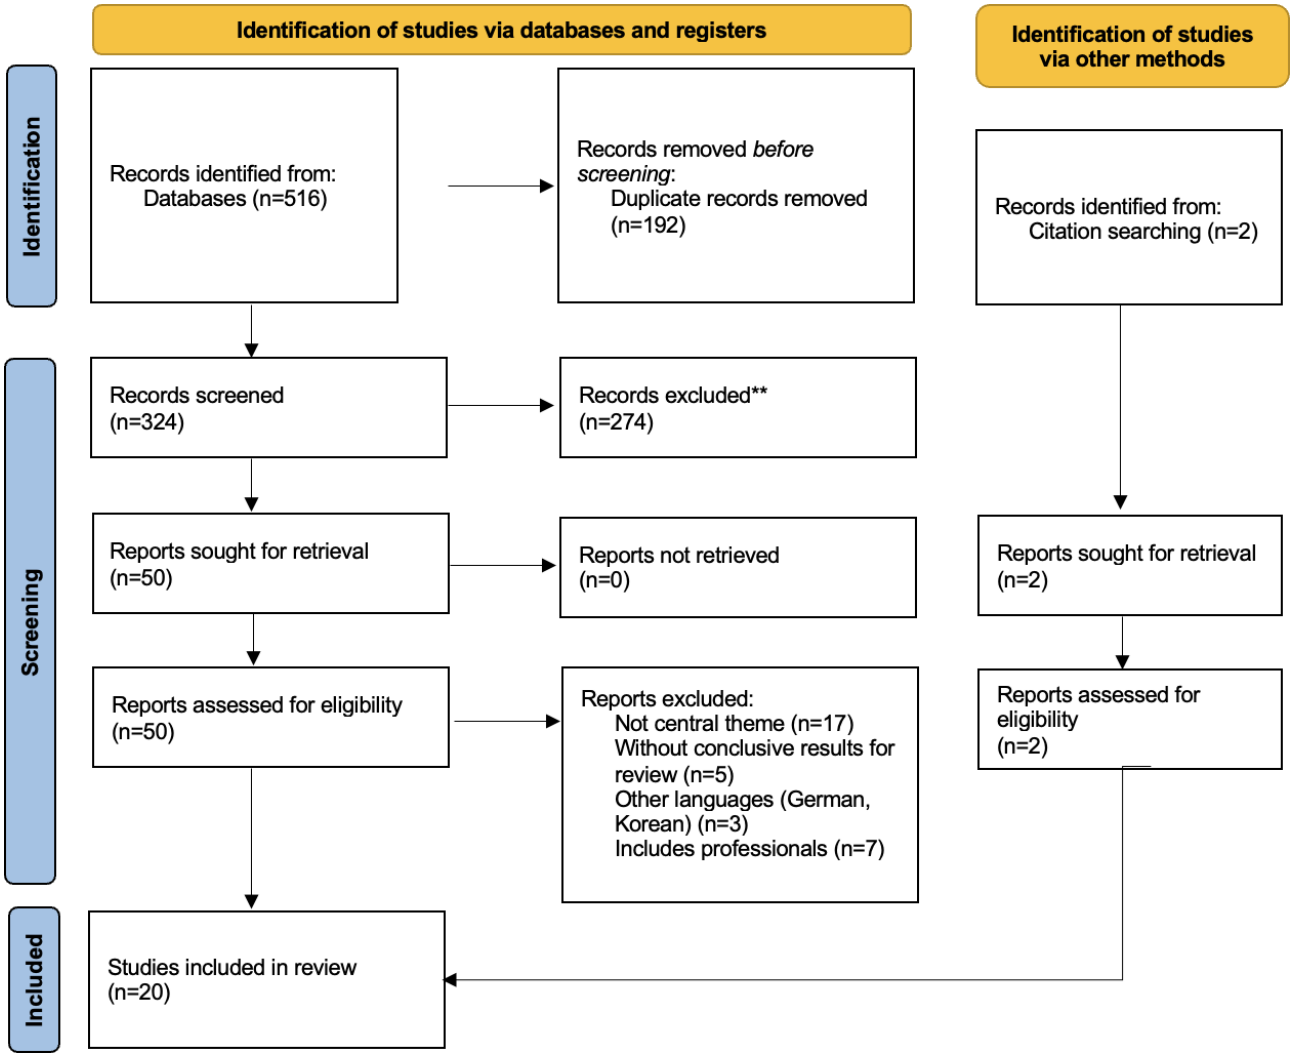
Article Selection, Methodological Quality Assessment, and Risk of Bias

The articles obtained were exported to the Zotero bibliographic manager. After removing duplicates, articles were selected by title and abstract during online sessions by 2 researchers. When discrepancies arose, another revisor was contacted for a final decision. Full texts of the remaining articles were obtained to assess eligibility. Two reviewers thoroughly assessed the full texts to determine study inclusion, resolving discrepancies through discussion and, when necessary, with the involvement of a third reviewer. Two reviewers determined that articles met eligibility criteria. References from secondary articles, such as reviews and scoping reviews, were also reviewed to assess their potential inclusion of those articles that met the objectives of this study. Those selected underwent a quality evaluation by 2 authors independently using the Joanna Briggs Institute (JBI) Critical Appraisal Tools [28] according to study design (the checklist for randomized controlled trials [RCTs] [29], the checklist for quasi-experimental studies [30], and the checklist for analytical cross-sectional studies [31]).

The methodological quality of all included studies was assessed independently by 2 reviewers using the JBI Critical Appraisal Tools according to the study design: the checklist for RCTs, quasi-experimental studies, and analytical cross-sectional studies. Discrepancies were resolved by consensus with a third reviewer. Studies meeting ≥60% of the applicable JBI criteria were included in the final synthesis. Considering that the JBI critical appraisal tools do not establish universal cutoff points for classifying methodological quality, leaving this decision to the discretion of review teams, a 60% threshold was applied as a pragmatic criterion to balance the inclusion of methodologically acceptable studies while avoiding overly restrictive exclusions, thereby ensuring the availability of sufficient evidence for analysis [28].

Data Extraction and Synthesis

The authors independently extracted data from the studies into a Microsoft Excel spreadsheet. The sheet recorded data on the author, year of publication, country, age of participants, type of study, objective, scales and instruments used, results and conclusions, limitations, safety aspects covered, type of simulation, types of interventions performed, and simulated cases (Table S7 in Multimedia Appendix 1 [32-51] and Table S8 in Multimedia Appendix 2 [32-51]). Given the diversity among the included studies, clinical and methodological heterogeneity (diverse domains, modalities, and durations), noncomparable instruments, and incomplete statistical reporting (missing effect sizes and variances), a narrative synthesis was conducted, guided by the principles of thematic content analysis.



Results

Study Selection

The selection process is shown in Figure 1.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram of study selection.

Characteristics of Included Studies

A total of 20 studies [32-51] met the inclusion criteria for this review. The primary characteristics of these studies are detailed in Table 3. The included articles were published between 2019 and 2024. The country with the highest number of studies was Korea with 6 studies [32,34,36,37,41,48], followed by the United States [32,40,45] and China [39,43,49], with 3 studies each. Spain [42,50] and Taiwan [46,51] contributed 2 studies each. Germany [35], Ireland [47], and Indonesia [38] contributed 1 study each. One study was led by an international team (Canada, England, Scotland, and Australia) [44]. For the purpose of counting, each of the 20 studies [32-51] was assigned to the country of the coordinating institution, and the multicountry study was considered as a single study with international participation.

Table . Characteristics of included studies.

Author (year), country	Participants	Type of study and assignment	Objectives	Data collection scales and instruments	Results and conclusions	Limitations
Breen et al [47] (2019), Ireland	Total 90: 45 nursing students 3rd course, 45 last-year medical students. Year: 2016.	ECA 3 groups: e-learning (E)[a], E+standard simulation (E+S)[b], competency-based progression simulation and e-learning (E+PBP)[c]. Randomized	To determine the effectiveness of a competency-based training (PBP)[d] for clinical communication.	National Early Warning Score (NEWS)[e] based on the ISBAR[f] tool	Communication competence was achieved by 2/29 (7%) in E, 3/23 (13%) in E+S, and 15/25 (60%) in competency-based progression. Competency-based training was significantly more effective (P<.001)	Single center; undergraduate sample; short training duration
Son and Kim [36] (2019), Korea	98 Nursing students. CG[g]: 41, IG[h]: 57 Course 3rd Year: 2017 Age: 22 - 23 Gender: Women	Quasi-experimental. Pretest-posttest design of nonequivalent control group. Convenience sampling	Effectiveness of communication education based on SEGUE[i] between students and patients.	Communication competence and effectiveness measured by a self-report questionnaire and by teacher and standardized patient ratings of the students	Intervention students showed significantly greater improvements in communication competence and efficacy than controls (In terms of performance, as assessed by lecturers and students, the P value is <.001, the standardized patient score is 0.042, and the communication effectiveness score is 0.004).	Single institution; small control group
Jeong and Kim [37] (2020), Korea	54 nursing students. IG: 26, CG: 28 Grade: 3rd Year: 2018 Age: 20 - 40 average 23 Gender: Women, only 1 man	Clinical trial (pre-post). Simple blind	Develop a fall simulation program using the SBAR[j] communication technique	Knowledge of falls and attitude toward falls scale, post-fall evaluation protocol (AHRQ[k]). GICC-15[l] and Dunsford adapted structured communication	SBAR-based simulation significantly improved structured fall-related communication compared with controls.	No long-term follow-up; single-blind design
Liaw et al [49] (2020), China	120 medical and nursing students. IG: 60, CG: 60 Grade: 3rd-4th year. Year: 2018. Mean age 22.17 (SD 2.07) years. Gender: Women (81, 67.5%)	RCT[m] (pretest-posttest) Randomized	To evaluate a team training program using VR[n] versus conventional live simulations on the performance of communication skills and teamwork	ATHCT[o] and ISVS[p]. Baseline, posttest, and 2 months after	Both groups improved teamwork attitudes; VR training was noninferior with higher follow-up ISVS.	Self-reported outcomes; single-center design
Sanko and McKay [33] (2020), United States	231 nursing students from 2016 (CG: 68), 2017 (IG: 85), and 2018 (CG: 78) patient safety courses.	Clinical trial (2 cohorts years different intervention and control groups). Convenience sampling	To assess whether exposure to simulation scenarios to enhance systematic thinking influenced adverse event reporting and the type	Simulated AERS[q]. System Thinking Scale (STS)[r]	Systems thinking scores increased significantly after simulation, and adverse event reporting improved (P<.001).	Single-site sample; simulated reporting system
Lee and Kim [34] (2020), Korea	194 nursing students. 47 teams (4 and 3 components) Course: higher level. Year: 2015 - 2016	Prospective observational convenience sampling	To examine the relationships between nursing students' team task performance and SBAR-R[s] communication.	Measurement of team task performance and communication using developed checklists based on SBAR-R	Higher SBAR-R scores were significantly associated with better team task performance (P=.004).	Single university; limited scope

Author (year), country	Participants	Type of study and assignment	Objectives	Data collection scales and instruments	Results and conclusions	Limitations
Wai et al [48] (2021), Korea	46 students: 19 medical, 27 nursing. Interprofessional teams. Grade: Final year medicine (5th), 3rd-4th year nursing. Gender: 63% female students.	Mixed methods convenience sampling	To compare the effectiveness of combined classroom plus clinical simulation versus clinical simulation alone on attitudes, perceptions, and teamwork performance.	HFAS[t] Survey. Teamwork performance using TBL-SAI[u] focus group interview	Both groups improved teamwork attitudes (P=.04) with no added benefit from classroom teaching	Small sample; limited power
Musharyanti et al [38] (2021), Indonesia	95 nursing students IG:55. CG: 40.	Quasi-experimental. Nonequivalent randomized control group.	To compare drug safety knowledge and skills after safety training with the 4C/ID[v] teaching method.	MCQs[w] and 2 checklists developed ad hoc on patient safety and medication administration	Intervention students achieved significantly higher safety knowledge and skills than controls (P<.001).	No baseline testing
Du et al [39] (2021), China	47 nursing students.CG:21, IG:26 Grade: 2nd Year 2019. Age 17 - 27 Gender: 44 women -3 men	Controlled trial. Simple blind.	To assess the risk of pressure ulcer development in 3 different scenarios	OSCE[x] adapted to different scenarios Pressure Ulcer Knowledge Assessment Tool (PUKAT 2.0)[y]	OSCE-based simulation significantly improved assessment performance (P<.001).	Small sample. Single center
Lee and Lim [32] (2021), Korea	30 nursing students. Grade: Final year. Year: 2018. Average age 22.17 Gender: women	Quasi-experimental (pre-post). Convenience sampling	Develop, implement, and verify the effectiveness of a simulation-based handover education program.	Communication tool adapted from SBAR. Knowledge questionnaire developed by authors. Self-efficacy (adapted questionnaire).PASS-BAR[z]	Simulation significantly improved handover knowledge, self-efficacy, and performance (P≤.001).	No control group; all-female sample
Craig et al [40] (2021), United States	83 nursing students. CG:35. IG:45 Grade: 3rd.	Quasi-experimental. Convenience sampling	To examine the effects of an educational strategy using a simulation program on medication management.	MSKA[aa] and MSCEC[ab]	Simulation significantly improved medication administration skills (P<.001).	Single-site study
Raurell-Torreda et al [50] (2021), Spain	93 nursing students. IG: 48, CG:45 Course: 3rd, 1 medical student in 5th year. Age: CG: 22.3±5.2- IG: 23.3±6.8 Gender: 78.5% women	Clinical Trial Randomized	Evaluate the impact of SBAR training on interprofessional teamwork skills (role-related and communication) and nontechnical skills.	KidSIM-TPS[ac] and CSET[ad] (nontechnical skills)	Intervention students showed significant improvements in teamwork behaviors (P≤.004).	Partial implementation
Park and Kim [41] (2021), Korea	91 nursing students. IG: 47, CG: 44. Final year of nursing Academic year 2018/19. Age: IG 22.59±1.23, CG 22.86±1.39 Gender:+77% women	Clinical Trial Randomized	Analyze the impact of simulated patient deterioration on situational awareness and patient safety competence-attitude.	SAGAT[ae] modified; PSCSE[af] modified.	Simulation significantly improved situational awareness and safety attitudes (P<.001).	Single university
Chen et al [51] 2022, Taiwan	54 students: 18 medical students and 36 nursing students Grade: 4th year nursing, 5th year medicine Year: 2019 Gender: 70% Women	Mixed methods Randomized	Determine the importance of interprofessional training on competence, teamwork attitudes, and safety.	MTP[ag], TBP[ah], TA[ai], and PSA[aj]	Both groups achieved comparable competence gains; qualitative data supported learning benefits	Small sample

[an]LCJR: Lasater Clinical Judgment Rubric.

[ao]CLECS: Clinical Learning Environment Comparison Survey.

[ap]G-IPAS: German Interprofessional Attitudes Scale.

The study designs varied, encompassing 8 RCTs [33,37,39,41,46,47,49,50], 11 quasi-gstudies [32,35,36,38,40,42-45,48,51], and 1 analytical cross-sectional study [34]. The participant samples predominantly consisted of undergraduate nursing and/or medical students at various stages of their training. The objectives of the studies commonly focused on evaluating the use of simulation-based training on competencies essential for patient safety, such as interprofessional communication, teamwork, and clinical reasoning. The studies that included only nursing students were 14 [32-34,36-46] and the remaining 6 were studies with a mixture of nursing and medical students [35,47-51], although one of them only included 1 medical student [50].

The total number of participants included was 2494. The study with the least participation grouped 30 students [41] and the one with the highest participation had 231 [42]. Most participants were women (more than 60%); in one of the studies, all participants belonged to a women's nursing school [41].

The studies were carried out from 2015 [34] to 2023 [35]; 5 of them did not report the age of the participants, and 4 did not report the academic year in which the participants were enrolled, their sex, or the year the study was conducted.

Measurement tools varied across studies. Only 4 studies used ad hoc questionnaires [34,36,38,44]. The remaining 16 studies [32,33,35,37,39-43,45-51] used validated instruments, some with contextual adaptations (eg, cultural and language modifications and scenario-specific items).

Characteristics of Interventions

The simulation-based training interventions detailed in the included studies were heterogeneous, as detailed in Table 4. Interventions ranged from single-session workshops (eg, 3.5 h) to multisession programs integrated into the curriculum.

The modalities of simulation used included high-fidelity simulators (HFS; n=9) [32,34,39-41,43,45,47,48], SPs (n=8) [35-39,48,49,51], virtual reality (VR; n=4) [44-46,49], role play (n=2) [38,50], and board simulations (n=1) [33]. Several studies combined HFS with SP or VR, so the categories are not mutually exclusive. The transfer of communication using a structured methodology between the team uses different strategies, such as SBAR (Situation, Background, Assessment, Recommendation) and SBAR-R [32,34,37,47,50] handover tools and KidSIM-TPS [50] teamwork frameworks, while other less commonly used techniques include the Kalamazoo communication checklist [46]. Structured communication with the patient is guided by the SEGUE (Set the stage, Elicit information, Give information, Understand the patient's perspective, End the encounter) framework [36]. These structured tools were detailed in the instruments and notes of Table 3.

XSL•FO
RenderX

Table . Characteristics of interventions.

Author (year), country	Modalities and type of simulation	Security aspects covered	Direction of effect	Type of intervention in the study	Case
Breen et al [47] (2019), Ireland	HFS[a]-HF[b]	Communication between professionals	Favors competency-based simulation	All groups 15 min training on the ISBAR[c] tool. Group (E[d]): HF room. Group (E+S[e]) work in mixed discipline pairs: telephone calls on 4 standardized cases (3.5 h). Group (E+PBP[f]): same training as group E+S, reached competencies	4 standardized clinical cases of acute patient deterioration
Son and Kim [36] (2019), Korea	SP[g]-HF	Communication with the patient	Favors simulation	CG[h]: Prebriefing + pretest (50 min), simulation 60 min, debriefing+posttest (50 min) afterward, and SEGUE[i]-based communication (30 min). IG[j]: SEGUE communication before	Standardized pediatric scenario, with mothers of 5-year-old children admitted to the hospital for acute gastroenteritis with fever
Jeong and Kim [37] (2020), Korea	SP-HF	Falls and communication	Favors simulation	IG: 3 educational sessions on falls communication and SBAR[k] method (theory, practice, and discussion). CG: training according to guidelines on patient care and transfer of information	Standardized patient falling out of bed
Liaw et al [49] (2020), China	VR[l] (simulated environment with avatar use) and live simulation (SP)-HF	Interprofessional communication and teamwork	Noninferior (VR vs live)	All groups received 3 h of team training on nurse-physician communication. IG: virtual environment and avatar, CG: SP. Each scenario lasted approximately 15 - 20 min and was followed by a 30-min facilitator briefing	Sepsis and septic shock scenario
Sanko and McKay [33] (2020), United States	Board simulation (board game) to teach and develop systematic thinking-LF[m]	Notification of incidents and adverse effects. System failures	Favors simulation	CG: Simulation scenarios. IG: 2017 course included a tabletop simulation“ Friday Night in the ER.”	Emergency care
Lee and Kim [34] (2020), Korea	HFS (IAM[n])-HF	Interprofessional communication	Positive association	Before the scenario training on SBAR-R[o] communication and election of the leader of each team. Development of the scenario in 2 times: before a call to a fictitious doctor and performance of the task in a team after receiving instructions by phone	Acute myocardial infarction emergency care

Methodological Quality Results

The overall methodological quality of the studies was moderate to high. Using the JBI Critical Appraisal Tools, RCTs generally scored between 9 and 13 out of 13 possible criteria, quasi-experimental studies between 7 and 9 out of 9, and cross-sectional studies met 6 to 8 out of 8 criteria, assessed according to JBI methodological standards for evidence synthesis [29-31].

Common strengths included clear description of inclusion criteria, valid measurement of outcomes, and appropriate statistical analyses. The most frequent limitations were related to lack of blinding of participants or assessors, incomplete follow-up, and limited control of confounding factors.

A summary of the appraisal results is presented in Table 5, while full details of the assessment can be found in Tables S2, S3, and S4 in Multimedia Appendices 3-5.

Table . Summary of methodological quality results.

Study design	Number of studies	JBI[a] tool used	Mean criteria met (%)	Common strengths	Common limitations
Randomized controlled trials	8	JBI RCT[b] Checklist (13 items)	85 - 100 (9, 13/13)	Clear objectives, valid measurement tools, and appropriate statistical analysis	Lack of blinding (3), small samples
Quasi-experimental studies	11	JBI Quasi-Experimental Checklist (9 items)	78 - 100 (7, 9/9)	Clear cause-effect design and reliable outcome measures	Absence of control group in some cases (3), incomplete follow-up (2)
Cross-sectional studies	1	JBI Analytical Cross-Sectional Checklist (8 items)	75 (6/8)	Clear inclusion criteria, valid exposure, and outcome measures	Confounding not always controlled

[b]RCT: randomized controlled trial.

Topics

The topics they discussed were communication, both interprofessional [32,34,46,47,49,50] as communication with the patient [36], teamwork [48,51] aspects related to medication, such as its administration [38,40,42] and notification of errors or adverse effects [33,35,43], systemic and organizational factors [41], falls [37], pressure ulcer prevention [39], patient deterioration [44], and various security aspects a mix of the above [45].

Mixed groups, with nursing and medical students, address topics such as interprofessional communication and teamwork [48-51]; only one of them addresses the issue of medication [35].

Most simulations aimed at developing communication and teamwork skills used high-fidelity modalities, including SP and mannequins [32,34,36,47,48,51] and VR environments [46,49]. One study used role-playing as the primary simulation modality [50].

To develop skills in aspects of medication administration, HFS has been used [40], role play [38], and simulated patients [38,42]. In the case of notification of medication errors and adverse effects, the simulation scenarios have used SPs and mannequins [35,43] and a board game [33]. The rest of the safety aspects discussed have used simulated patients or mannequins, except the study on patient deterioration, which has used VR technology [44].

High-fidelity simulation through HFSs, VR, and SPs predominated across studies. However, low-fidelity approaches, such as role-playing, were also used, either alone or combined with other modalities, particularly in interprofessional communication [50], medication administration [38], and incident or system failure reporting [33].

Safety Outcomes

In general, almost all studies link training through simulation scenarios with an improvement in safety-related skills and knowledge [32-47,50]. One study directly compared live (face-to-face) simulation with immersive VR simulation in scenario-based training [49]. The comparator was therefore 2 different simulation modalities rather than simulation versus traditional teaching. No statistically significant differences were found between live and VR simulation in the development of teamwork and communication skills. These findings suggest that VR-based simulation may represent a comparable alternative to live simulation for fostering these competencies.

Simulation training complemented by other techniques (lectures, presentations, debates, and demonstrations) achieves better results than simulation training alone for improving patient safety competency among nursing students [43]. However, the effects of a blended classroom plus clinical simulation versus clinical simulation alone on teamwork attitudes did not further improve teamwork attitudes, perceptions, and performance in medical and nursing students compared with clinical simulation alone [48]. A quasi-experimental study comparing traditional clinical practice, manikin-based high-fidelity simulation, and screen-based virtual simulation (n=193) found no significant differences in cognitive outcomes between groups [45]. However, students in the manikin-based simulation group achieved significantly higher scores than those in the traditional clinical group in several competency domains measured by the Creighton Competency Evaluation Instrument, including communication (effect size=0.52; P=.04), although no significant differences were observed in the Patient Safety

XSL•FO
RenderX

domain. These findings suggest that the type of simulation experience may influence specific clinical competency outcomes [45].

Only 2 studies followed up over time after training [46,49]. In one study, the results were better than before after 1 week of practice [46]. A RCT compared immersive VR simulation with conventional live simulation in 120 medical and nursing students. Both modalities significantly improved teamwork attitudes and interprofessional socialization immediately postintervention. At 2-month follow-up, only the VR group maintained a significant improvement in Interprofessional Socialization and Valuing Scale scores (P=.047), although no statistically significant differences were found between groups at any time point, suggesting comparable effectiveness [49].

Two studies evaluated competencies using Objective Structured Clinical Examination–based assessments. In one study, 47 second-year nursing students receiving simulation-based training achieved significantly higher scores in pressure ulcer risk assessment than those receiving standard instruction (mean 29.04, SD 6.00 vs mean 12.38, SD 4.15; P<.001) across 3 simulated scenarios using SPs [39]. In another randomized educational trial including 90 nursing and medical students, competency-based simulation combined with e-learning led to higher communication competence (60%) compared with e-learning alone (6.9%) and standard simulation (13%), using a clinical structured communication tool [47].

Discussion

Principal Findings

This systematic review aimed to evaluate the effect of simulation-based education on patient safety outcomes in undergraduate nursing students, to identify the patient safety domains addressed through simulation, and to describe the characteristics of simulation-based educational interventions. Overall, the findings suggest that simulation-based education is associated with improvements in several competencies related to patient safety, particularly communication, teamwork, medication safety, and the recognition and reporting of clinical incidents. High-fidelity simulation predominated among the included interventions, with 16 studies using this modality [32,34-43,45,47,48,50,51]. In addition, the incorporation of VR [35,37,40] expands the range of clinical scenarios that can be recreated in educational environments and may facilitate the development of knowledge and skills related to patient safety [43].

Among the patient safety domains addressed, communication and teamwork were the most frequently studied. Several studies reported improvements in these competencies following simulation-based training among nursing and medical students [38-42]. Simulation scenarios provide opportunities for students to practice interprofessional collaboration and structured information transfer in controlled learning environments. Structured communication tools, such as SBAR and its adaptations, were frequently incorporated into simulation scenarios and were associated with improved team coordination and information transfer [32,34,37,46,47,50]. Similarly, structured communication strategies have been shown to improve communication between students and patients [36]. Communication-focused simulations often involved interprofessional scenarios in which students practiced structured communication during clinical deterioration or emergencies, strengthening collaborative decision-making between professionals [47,49,50].

Medication safety was another frequently addressed domain. Three studies evaluated students' ability to safely administer medications, identify potential errors, and follow appropriate safety procedures [38,40,42]. Simulation provides a controlled environment in which students can practice medication administration while recognizing potential safety risks without endangering real patients. In addition, simulation-based education was associated with improvements in the reporting of adverse events and medication-related incidents [40,42]. Other 3 studies also explored the development of systems thinking and incident reporting competencies through simulation scenarios focused on adverse event reporting or clinical error disclosure [33,35,43]. These activities encouraged students to recognize systemic factors contributing to patient safety incidents and to adopt a nonpunitive perspective toward error management.

This review also highlights the diversity of simulation modalities used to address patient safety competencies. SPs were commonly used to train communication with patients [36], reporting incidents such as falls or medication errors [35,37], pressure ulcer prevention [39], teamwork and interprofessional communication [49,51], and medication administration [38,42]. High-fidelity simulation using mannequins was the most frequently used modality [32,34,39-41,43,45,47,48]. VR simulations were also used, particularly in scenarios focused on communication and teamwork [35,46,49].

Although high-fidelity simulation was widely used, lower-technology simulation approaches also demonstrated positive learning outcomes. Role-playing, tabletop simulations, and screen-based virtual simulations improved competencies related to communication, systems thinking, and incident reporting [33,38,50]. These findings suggest that simulation-based education can be implemented across a variety of educational settings, including institutions with limited technological resources. In addition to simulation modality, the instructional design of the intervention influenced outcomes. One study reported greater improvements when simulation was integrated with complementary educational strategies such as lectures, structured feedback, or online modules [43].

Comparison With Previous Literature

The findings of this review are consistent with previous literature highlighting the educational value of simulation in health professions education [5252]. Improvements in communication and teamwork competencies observed in the included studies align with recent meta-analyses emphasizing the importance of interprofessional education for improving role understanding and collaborative practice among health care students [53,54]. Improvements in these competencies are particularly relevant to patient safety, as failures in communication and teamwork are frequently associated with preventable adverse events in

XSL•FO
RenderX

clinical practice. Interprofessional simulation experiences have been shown to strengthen role clarity and collaborative practice, thereby promoting safety-oriented behaviors among future health professionals [54].

Similarly, the improvements observed in medication safety practices are consistent with previous reviews suggesting that simulation-based education can be an effective method for improving patient safety competencies [24]. Evidence from systematic reviews also indicates that the use of SPs may enhance communication skills, learning outcomes, and problem-solving abilities in health professions education [23]. Previous reviews have also reported improvements in knowledge, confidence, and clinical skills following simulation-based learning [21,22], although many of these studies did not specifically focus on patient safety outcomes. Compared with earlier literature, the present review provides a more focused synthesis of evidence regarding the use of simulation-based education to address patient safety competencies in undergraduate nursing students.

The findings of this review also suggest that the use of different simulation methods and varying levels of fidelity, as observed across the included studies, can be similarly effective for developing competencies related to patient safety. These results are consistent with previous literature, indicating that the effectiveness of simulation-based education does not depend solely on the level of technological fidelity. Studies comparing high-fidelity simulation with alternative teaching strategies, such as written case studies, have not demonstrated clear advantages of high-fidelity simulation alone for improving critical thinking skills in nursing students [55].

Sustainability of Training Effects

Despite the positive outcomes reported in most studies, the long-term sustainability of simulation-based training effects remains unclear. Only 2 studies included follow-up assessments after the intervention, with relatively short follow-up periods of 1 week and 2 months [46,49]. Consequently, it is difficult to determine whether the improvements observed are maintained over time or translate into sustained behavioral changes in clinical practice. This limitation is particularly relevant because previous research on medication safety suggests that safety-related competencies may decline if they are not reinforced through continued practice and training [56].

Practical Implications for Nursing Education

The findings of this systematic review have several important practical implications for undergraduate nursing education. Overall, the evidence indicates that simulation-based education is an effective strategy for developing key patient safety competencies, particularly in communication, teamwork, medication safety, and error recognition [32-47].

The results support the systematic integration of simulation-based learning into nursing curricula, rather than its use as an isolated or supplementary teaching activity. Simulation-based interventions embedded within educational programs improved students' patient safety competencies [40,42,43,45,46]. Simulation scenarios focused on real-world patient safety challenges enable students to apply theoretical knowledge in a safe and controlled environment [39,41,44].

The impact of structured communication tools, such as SBAR, ISBAR (Identification, Situation, Background, Assessment, Recommendation), and SEGUE, suggests that these frameworks should be explicitly incorporated into simulation-based training [32,34,36,37,47]. The use of these tools during simulation may reduce communication-related errors and enhance patient safety.

In terms of the characteristics of the simulation, the included studies used various methods, including manikin simulation, SPs, virtual simulation, role-playing, and tabletop simulation. The level of fidelity within these modalities varied between low, medium, and high, depending on the technological complexity and degree of clinical realism described by the authors. While experiences with a higher level of technological fidelity were common, several studies demonstrated that modalities with lower technological requirements, such as role-playing or tabletop simulation [33,38,50], as well as basic virtual environments [44-46,49], could also be effective in improving patient safety knowledge and skills. These findings suggest that meaningful educational outcomes can be achieved with modalities that have lower technological requirements, which is particularly relevant for institutions with limited resources.

Current Gaps in the Literature

Even with mounting evidence backing simulation-based training in nursing, this review identified several important gaps in existing literature. One of the most significant limitations is the lack of long-term follow-up. Only 2 of the studies included assessed outcomes beyond the immediate postintervention period, with follow-up periods of 1 week and 2 months, respectively [46,49].

Another gap relates to study design and methodological rigor. Although RCTs were included, 9 of studies used quasi-experimental designs with convenience sampling and relatively small sample sizes [24,25,29-31,33-36]. In addition, blinding of participants and assessors was rarely reported. Also, studies used a wide range of instruments to assess patient safety competencies, including self-developed questionnaires and modified scales [25,27,29,33,35].

Geographically, most studies were conducted in high-income countries [22-42], with limited representation from low- and middle-income settings, indicating a lack of global diversity in the evidence base.

Recommendations for Future Research

Future research should address the limitations identified in this review. Longitudinal studies are needed to assess retention and maintenance of competencies. The use of standardized tools and methodologically sound, multicenter clinical trials would improve external validity and avoid bias. On the other hand, studies comparing the efficiency and cost-effectiveness of different simulation modalities would help guide curricula and resource allocation. It would be necessary to include other educational contexts in low- and middle-income countries in order to apply the results and guide nursing training plans. The

XSL•FO
RenderX

limited reporting of facilitator preparation across studies highlights the need for future research to examine the role of educator training in simulation-based patient safety education.

Limitations

It is important to consider the limitations of this study when interpreting the results. First, there is a considerable degree of heterogeneity between the studies, not only in terms of the type of intervention and duration, but also in terms of the training of the participants, experience, and origin. Additionally, the variability of measurement instruments, convenience samples, and the use of self-reported data may introduce bias. Furthermore, the restriction of the search to studies published in English, Spanish, and Portuguese may have resulted in the exclusion of some relevant studies. The criteria used to establish the cutoff point in the methodological quality assessment may have influenced the final selection of evidence included.

The search strategy was limited to the terms “patient safety” and “safety,” which may have led to the exclusion of relevant studies addressing patient safety outcomes. Although additional manual screening of references was performed to identify potentially relevant studies, this restriction may have reduced the sensitivity of the search.

Although a systematic approach to study selection ensures the quality of the evidence, it may result in the omission of relevant research that, although less rigorous, could offer valuable insights.

Conclusions

Despite considerable discrepancies between individual studies, simulation is an important tool that empowers nursing students to identify, mitigate, or eliminate potential risks to patient safety. The use of simulation methodology facilitates the acquisition of essential competencies, including communication skills, teamwork, medication administration, and error detection and adverse effect recognition. These skills are crucial for ensuring patient safety upon entering the professional workforce. The use of high-fidelity simulation enables the recreation of clinical scenarios, facilitating the integration of theoretical and practical training, and thus the development of skills and a more comprehensive integration of knowledge.

Simulation-based education improves nursing students’ competence in key safety domains (communication, teamwork, medication safety, and error recognition), thus contributing to improved patient safety outcomes.

Abstract

Background: The role of nursing informaticians is well-established in countries like the United States, Canada, and Australia, supported by competency frameworks and educational programs that enable nurses to lead technological integration in health care. However, in Spain, this role is not formally recognized, and specialized university training is scarce, creating a significant gap in digital health leadership among nurses.

Objective: The study aimed to analyze the international landscape of the nursing informatician role, comparatively focusing on the situation in Spain, to subsequently identify the specific gaps for its implementation through experts' views and insights.

Methods: First, a scoping review following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines was conducted in English and Spanish using scientific evidence searched in PubMed, Scopus, CINAHL, and Web of Science from 2018 to the present, as well as gray literature on the topic. A total of 55 published studies were included after screening 1356 records and 10 gray literature documents. Subsequently, findings were validated through a gap analysis comprising a panel of 10 experts selected according to their experience in digital literacy.

Results: The review identified 6 core competencies for nursing informaticians: information management, cybersecurity, patient safety, evaluation and development of clinical information systems, leadership and coordination of digital tools, implementation of new technologies and specialized applications, and education and digitalization in health. Internationally, training is delivered via postgraduate programs, certifications, and leadership initiatives. Experts validated the relevance of these competencies for Spain (rated 5/5) and the applicability and desirability of implementing training programs (rated 4.8/5). Key barriers identified were the lack of official recognition, scarce training, and organizational resistance to change.

Conclusions: There is a contrast between the established role of nursing informaticians internationally and its absence in Spain. The lack of a formal framework and specific training programs is the primary barrier. Implementing validated competencies and tailored educational strategies is crucial for Spain to advance its digital health transformation and empower nursing leadership in technology.

nursing informatics; nursing informaticians; enfermeras especialistas en sistemas de información; digital health; competency-based education

Introduction

Global Perspective

Nursing informatics (NI) is a discipline that has gained relevance in recent years due to the increasing integration of information and communication technologies. The definition of NI includes the integration of information technologies in patient care and the clinical setting. Digital transformation facilitates and enhances diagnosis, data management, information, and optimization of processes. This can lead to improved quality of care and efficiency of the health care system [1]. Within this transformation, NI emerges as a crucial discipline that integrates

XSL•FO
RenderX

nursing science, information technology, innovative technologies, and data analytics to manage and communicate data, information, technology integration, and nursing practice [1,2]. The professionals who lead this charge are nursing informaticians (in Spanish "Enfermeras Especialistas en Sistemas de Información" or "Enfermeras Informáticas" [EESIs]), who serve as the vital connection between clinical practice, information systems, and technical teams [3].

Literature Review

In countries like the United States, Canada, and Australia, this advanced role is well-established and robustly supported. The presence of professional bodies such as the American Medical Informatics Association, the Healthcare Information and Management Systems Society, the Canadian Nursing Informatics Association, and the Health Informatics Society of Australia provides a structured framework for professional development. These frameworks help define the role of nursing informaticians as a link between clinical practice and information systems that analyze, design, implement, and evaluate health information technologies. "Nursing informatician" is a generic term that includes variations depending on the formative level and leadership. For example, "nurse informaticist" or "nursing informatics specialist" is a common and specific job title for a professional with advanced knowledge [4]. Other alternatives are "chief nursing informatics officer," an executive role that provides an informatics strategy focused on nursing practice, and "chief X informatics officer," which includes clinical informatics leaders from various disciplines [5]. Furthermore, universities in these nations have prioritized the integration of informatics competencies into nursing curricula, empowering graduates to lead the use of technology in clinical practice [6]. This combination of professional communities, academic programs, and defined competency frameworks enables nursing informaticians to lead high-impact projects in the digital transformation of health care systems.

This leadership is present in several key areas. For instance, nursing informaticians can contribute to the development of interactive digital platforms to supervise and ensure the quality of clinical placements. In this context, a user-centered design has proven fundamental to successful adoption by supervisors and students [7,8]. Their expertise becomes essential in guiding institutions through the creation or development of e-learning platforms, where success depends on a broad and systematic analysis of needs rather than on technical specifications alone [9]. Moreover, they command the "co-creation" of educational resources, mostly virtual teaching packages. This methodology involves end users in the design process, creating training tools perceived as relevant and useful by them [10].

Emerging technologies, such as artificial intelligence, language processing models, big data, and 3D printing, can also be part of these nurses' competencies. However, without appropriate training and a legislative framework, the integration of these advances into clinical practice can be challenging. Their training enables them to stay updated on technological advancements [11].

These examples of NI competencies that are commonly assumed in the international context by their role underscore a profound functional gap in Spain. There, the nursing informatician's role is not formally recognized, and relevant university training is scarce. This absence raises a key question: "Why is the concept of nursing informaticians developed and implemented globally while absent in Spain?" As experts point out, digital health in the country faces significant challenges due to a lack of specialized training and a defined competency framework for nursing in this field [8]. This requires defining specific competencies that go beyond just using clinical information systems [12]. Furthermore, nursing students' basic digital literacy in their current studies is insufficient [13], so specialized training becomes essential to prepare future nurses to use and integrate technology in health care [14].

Research Objectives

Given the differences between international and national paradigms, a comprehensive analysis was required. This led to a 2-phase study design comprising 2 objectives: the first was to analyze the international scientific and gray literature on the nursing informaticians' role, comparatively focusing on the situation in Spain. The second objective consisted of validating these findings by identifying the specific barriers and opportunities for implementing the role in Spain according to experts' views and insights.

Methods

In line with the objectives, the design was divided into 2 phases: the first was related to the main objective for the scoping review, and the second phase focused on the second aim related to a gap analysis.

Phase 1

A scoping review was chosen to conduct a comprehensive analysis of existing literature, identify research gaps in publications, and examine the diverse evidence surrounding the nursing informaticians' role, as well as gray literature. Analysis is required before drawing specific conclusions [15]. To guide this review, a research question was framed using the population, concept, context framework:

- Population: the nursing profession and, specifically, the role of nursing informaticians
- Concept: professional roles, competencies, training models, barriers, and facilitators for the implementation of the nursing informaticians' role
- Context: the international health care landscape, considering experienced countries in NI, is used as a benchmark to analyze the existing gap in the Spanish health care system

The scoping review was conducted following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines (Checklist 1) [16]. A comprehensive search strategy was developed to reflect the international scope and the specific focus on Spain. Key terms in both languages, English and Spanish, included "nursing informatics," "nursing informatics," "nursing informaticians," "informática aplicada a la enfermería," "enfermeras especialistas en sistemas de información," and "enfermería informática." The search was performed for articles published from 2018 to the present across high-impact

XSL•FO
RenderX

databases: PubMed, Scopus, CINAHL, and Web of Science. Filters for language, document type, and full-text accessibility were applied. To ensure a comprehensive overview, the search was supplemented with gray literature from international NI associations, relevant institutional documents, and university curricula in Spain related to the discipline.

Inclusion and Exclusion Criteria

Articles selected during the methodological analysis process contained one or more of the keywords corresponding to NI and nursing informaticians. In the next step, the content of the screened articles was studied to determine their relevance to the current study.

During the screening process, the following exclusion criteria were applied to scientific articles:

- Nonspecific article content despite mentioning the search terms
- Low academic quality: studies with inconsistent methodology or insufficient bibliographic support
- Full text unavailable
- Article irretrievable from repositories

After screening, a review of all literature was conducted following the steps recommended by the Joanna Briggs Institute (Table 1) for conducting scoping reviews. This process included identifying the research question, searching for relevant evidence, selecting studies, extracting data, and presenting the results [15].

Data Extraction and Analysis

This review was conducted through manual data extraction by the researchers to maximize the quality of information selection. The search strategy was supplemented by reviewing gray literature, obtaining documents from relevant associations, and white papers on NI around the world. Some were deemed eligible, and others were excluded after a screening process. The data were then processed in an ordered format with the help of the Microsoft Office suite. This helped create a much more sensible and accurate starting point for the analysis using that software. This method likely ensures a high-quality review of the literature and, in turn, provides a rigorous summary of the evidence.

Artificial intelligence was used on a very limited basis to make only editorial corrections within the final manuscript in order to enhance writing quality and correct grammar, spelling, and structure in different article files. These tools were not used to extract or analyze results. This approach ensures the relevance and currency of the extracted data within the study context.

Phase 2

This phase aimed to validate the scoping review findings through a gap analysis, consisting of a cross-sectional expert panel consultation survey with quantitative items and related qualitative open-ended questions (this survey or questionnaire can be found in Multimedia Appendix 1). For this purpose, a panel of 10 national experts in NI was assembled. All participants volunteered to participate and were recruited through an open call issued by the authors. Experts were selected based on the following criteria: (1) 10 or more years of experience related to health and digital literacy environments in Spain, (2) extensive training in digital literacy, and (3) peer-recognized expertise within their professional field. Their sociodemographic characteristics are detailed in Table 2.

XSL•FO
RenderX

Table . Experts' sociodemographic characteristics.

ID	Gender	Age (y)	Years of experience	Highest education level	Current position	Main area of expertise	Autonomous community
E1	Male	46	22	PhD	University professor	Digital health literacy	Madrid
E2	Male	53	29	PhD	Director of Digital Strategy	Hospital information systems	Catalonia
E3	Female	49	25	Master's	Clinical Informatics Specialist	Clinical workflows and EHR[a]	Andalusia
E4	Female	57	31	PhD	Senior eHealth Researcher	Telemedicine and patient care	Madrid
E5	Female	40	16	Master's	Informatics Unit Supervisor	EHR implementation	Valencian Community
E6	Male	32	15	PhD	Digital Health Consultant	Data governance and security	Valencian Community
E7	Female	43	19	PhD	Health care Innovation Manager	Semantic interoperability	Galicia
E8	Female	56	33	PhD	Dean of Health Sciences	Ethics and legislation in eHealth	Castile and León
E9	Male	45	20	Master's	Advanced Practice Nurse	Big data and health analytics	Valencian Community
E10	Female	53	27	PhD	Director of Nursing Services	Leadership and digital change	Andalusia

[a]EHR: electronic health record.

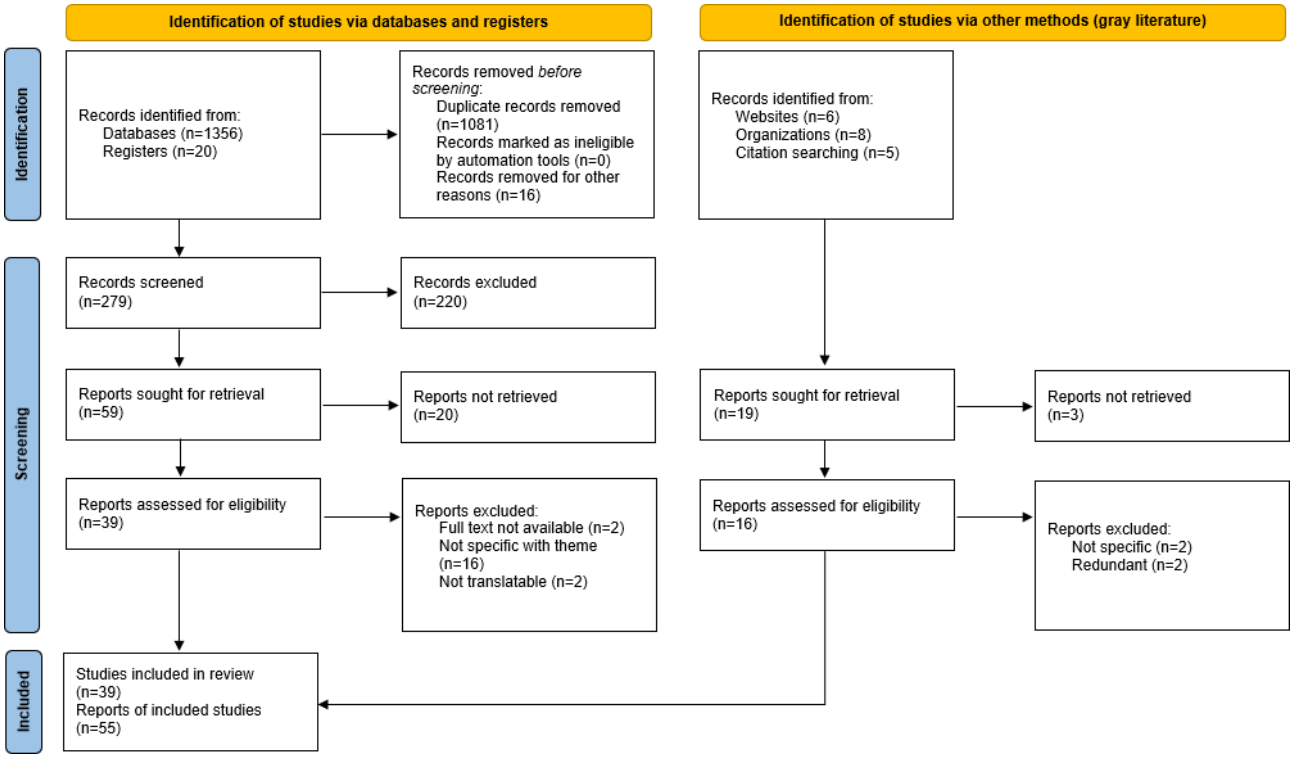
Sample size was determined based on the principles of purposive sampling and data saturation. This approach is consistent with the methodological literature on Delphi studies and expert panels, where a sample of 10 to 20 highly specialized participants is considered sufficient to achieve a comprehensive depth of information and reach thematic saturation [50]. Qualitative comments from the experts were analyzed through a simplified thematic analysis to identify relevant information not captured by quantitative items. The quality and richness of the data provided by these experts were prioritized over a larger, less specialized sample. To ensure objectivity, anonymity among experts was maintained so that none of the experts knew the identity of the rest of the panel.

Ethical Considerations

The scoping review conducted in this study exclusively used publicly available data and literature. Therefore, it did not require ethical approval. For the gap analysis, all participating experts were informed of the study's objectives and provided written consent to participate before answering the questionnaire. Anonymity and confidentiality of their responses were guaranteed throughout the process. No compensation was provided to the participants.

Trial Registration

The results of a health care intervention on human subjects are not reported in this study; therefore, registration in a clinical trials registry was not applicable.



Results

Scientific Literature Review

The scoping review included 55 published studies (the full list is available in Multimedia Appendix 2). The literature review identified an increasing scientific output internationally on NI and the role of nursing informaticians (see the PRISMA [Preferred Reporting Items for Systematic Reviews and Meta-Analyses] flow diagram [Figure 1] for the process of the complete search [16]). However, production in Spanish is significantly lower.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

Academic Training

During the study and after an exhaustive literature analysis, several training methods were identified that are used to impart the necessary knowledge and skills to nursing informaticians in clinical practice (Table 3).

Table . Academic training.

Academic training	Description	References
Undergraduate and postgraduate programs	Degrees incorporating health information systems, data analysis, and emerging technologies.	[1,17-19]
Research projects and theses	Advanced training (Master's/PhD) focused on investigating specific NI[a] problems to develop analytical skills.	[18]
Practical training and rotations	Supervised clinical placements allowing the application of theoretical knowledge in real-world settings.	[2,17,19]
Simulations and labs	Use of EHR[b] simulators and informatics laboratories for safe, interactive learning.	[17,26,27]
Continuing education	Professional certifications, seminars, and workshops for updating skills (eg, cybersecurity, data management).	[2,20,23,24,29]
Leadership programs	Mentorship initiatives for emerging leaders (eg, Alliance for Nursing Informatics Emerging Leaders Program).	[2,25]

[a]NI: nursing informatics.

[b]EHR: electronic health record.

In summary, training in NI is conducted through a combination of academic programs, competency models, continuing education, clinical placements, simulations, online courses, seminars, workshops, research projects, and leadership training. These training methods must be developed to increase knowledge about NI [30] and evaluated to ensure that nurses acquire the necessary competencies to effectively implement and use information systems in clinical practice, as well as to integrate new technologies into the clinical environment [31].

Competencies

As a result of the consulted literature and its exhaustive analysis, essential competencies for nursing informaticians have been identified [32,33]. These competencies are fundamental to

XSL•FO
RenderX

understanding the functions they would fulfill in this nursing leadership role within the Spanish health care system. They are structured into 6 general competencies (Table 4).

Table . Competencies.

Competencies	Description	References
Information management	Includes the collection, storage, organization, and analysis of health data. Nursing informaticians must ensure patient privacy (applying current regulations) regarding their private information at all times. It also implies establishing standardized nursing documentation models for efficient and accurate information (NI[a] process), as well as the use of standardized taxonomies. Measures nursing care complexity and ensures privacy.	[35,36,51,52]
Cybersecurity and patient safety	The integration of new technologies must prioritize patient safety, minimizing risks. In turn, the accuracy and reliability of data must be guaranteed, as well as their confidentiality.	[36,37]
Evaluation and development of clinical information systems	Analysis and management, creation, evaluation, and modification of hospital information systems to improve the quality of care. They must be practical and relevant to nursing practice. They must also integrate connectivity with new technologies.	[36]
Leadership and coordination of digital tools	Leadership in digital communication and patient care management using advanced digital tools are important competencies.	[5,14,36]
Implementation of new technologies and specialized applications	Integration of artificial intelligence, 3D printing, metaverse, big data, and robotics. Nursing informaticians as technological experts integrating and promoting these technologies.	[37-40]
Education and digitalization in health	Continuing education in new technologies is crucial to prepare health professionals. Nursing informaticians must be trained to transmit knowledge in information technologies and the use of emerging technologies to health care professionals in their environment.	[41,42]

[a]NI: nursing informatics.

Contextual Framework

The successful implementation of nursing informaticians requires the definition, training, and aptitude of nurses in digital competencies within a specific contextual framework. This framework must include both generalist nurses and nursing informaticians [17,38,47].

All nurses must have the opportunity to receive training and qualifications as expert users to fully leverage the possibilities offered by technology while also knowing how to mitigate information overload [5,38]. Generally, younger nurses tend to possess more positive training, education, and attitudes toward technology; however, all professionals must be provided with opportunities adapted to their existing knowledge to undergo training in digital transformation [17,38]. Strategies must be established to combat computer illiteracy, structural problems (such as lack of staff and financial resources), and limited access to new technologies, which constitute the most common barriers. Likewise, these conditions must be met while ensuring the privacy and security of obtained data, servers, and devices to guarantee the safety of both patients and professionals [28,38].

Specific leadership roles in digital transformation will be assumed by nursing informaticians [5,17]. Their objective must be to increase system efficiency and improve the quality of care through evidence-based data in an interdisciplinary, coordinated, and patient-centered manner [4,5,17,24].

Benefits

Based on the literature, the implementation of the nursing informaticians' role in Spain presents several potential benefits, inspired by the experiences of other countries (Table 5).

XSL•FO
RenderX

Table . Benefits.

Benefits	Description	References
Improved management and use of health information systems	Nursing informaticians combine clinical nursing knowledge with an understanding of information sciences, acting as a connection between nurses and technical teams	[1,3,4,23,28,32,33,47]
Leadership in the adoption of new technologies	Responsible for developing and implementing ICTs[a] in the clinical setting	[3,8,14,22,24,38,47]
Optimization of the development and implementation of the electronic health record	Nursing informaticians ensure that EHR[b] systems are designed to facilitate compatibility with care and traceability of clinical practice	[3,18,30,38,42]
Contribution to nursing research	Participating in the research and implementation of digitalization solutions, as well as the collection, processing, and interpretation of large datasets	[6,14,15,28,29,40,46]
Effective application of the NP[c], care complexity, and resource allocation	Strengthening evidence-based practice and consolidating nursing as a science. Nursing informaticians can ensure the effective application of the NP and promote the use of standardized taxonomies. Furthermore, the use of structured data allows quantifying care complexity. Consequently, nursing informaticians become essential for designing systems that move from operational documentation to predictive decision-making	[8,19,23,35,42,51-53]

[a]ICT: information and communication technology.

[b]EHR: electronic health record.

[c]NP: nursing process.

Barriers

Potential barriers to its implementation have been identified (Table 6).

Table . Barriers.

Barriers	Description	References
Lack of formal recognition and specific training programs in Spain.	Currently, training in NI[a] is limited.	[13,19,25,32,33,35,42,48]
Need to improve digital literacy in nursing.	Current competencies in applied informatics are insufficient.	[8,13,19,26,35,38,42]
Challenges in the integration of technologies and systems.	Includes a plurality of terminologies and a lack of experience among nurses.	[6,43,49]
Absence of a national digital health competency framework specific to nursing.	Essential for defining and acquiring the competencies of nursing informaticians.	[6,17,43]
Resistance to change and a lack of understanding of the value of structured data.	On the part of some professionals.	[17,26,42]
Limitations in accessing and using clinical nursing data.	Depend on electronic records.	[2,6,13,42,43]
Need for investment and resources.	For the training and integration of these professionals.	[5,6,14,20,38,46]

[a]NI: nursing informatics.

Expert-Validated Gap Analysis

Following the scoping review, the opinions of a panel of 10 experts in the field of NI were gathered. Using a form, they evaluated the results retrieved from the scoping review based on their extensive experience. They rated items on a scale from 1 (strongly disagree) to 5 (strongly agree) and wrote down their perspectives on each aspect from the scoping review.

Academic Training

The applicability and desirability of implementing specific training programs for nursing informaticians were

XSL•FO
RenderX

overwhelmingly rated very positively by the experts (4.5/5). The proposals for their implementation are diverse:

- Continuing education: the importance of "continuing education from professional associations" is emphasized, including "practical workshops" and accessible courses. A "hybrid training model, in small teams, by knowledge level and very real needs applied to the specific practice of the work area" is proposed.
- Methodology: the development of a "modular and progressive curriculum, with training in digital competencies from the degree level, interdisciplinary master's programs, and accredited continuing education, integrating mixed methodologies (in-person and online), digital clinical simulations, and practicums in real health care settings" is valued.
- Collaboration: the need for universities, in collaboration with professional associations and technology companies, to work in symbiosis to develop the most relevant content is emphasized.
- Implementation phases: some experts suggest "starting with pilot experiences in hospitals that are already digitized" or "initially through postgraduate training, possibly due to low demand," to later integrate it into the undergraduate degree.
- Culture and recognition: the importance of "creating the culture and the social or professional symbolic image of this role before its future implementation" and the need for a "prior change in the culture of digital literacy among nursing professionals" are highlighted.

Competencies

The competencies described in the scoping review received the highest rating (4.7/5), along with the benefits. The experts consider that the competencies identified for nursing informaticians are "highly relevant and applicable within the Spanish health care system, as they directly respond to current and emerging needs":

- Key benefits: it is highlighted that they are crucial for "patient safety" and the "improvement in quality of care, potential for research, and analysis of results."
- Adaptation to the environment: it is acknowledged that they must be "adapted to our reality: limited resources, differences between autonomous communities, and the need for more practical training."
- Transdisciplinary role: it is suggested that nursing informaticians "should be integrated into transdisciplinary teams in research, as well as in management or decision-making regarding the design, development, validation, and implementation of new technologies."
- European trend: it is pointed out that "they correlate with basic European digital competencies, therefore showing traceability with our educational system."

Benefits

There was broad recognition among experts (4.7/5) of the multiple benefits that implementing the EESI role would bring:

- Improved quality and efficiency: an "optimization in the management and use of health information systems" is expected, improving "care continuity, interoperability […] and the traceability of care."
- Leadership in digital transformation: EESIs would provide "key leadership in the adoption and implementation of information and communication technologies." One expert believes that "nursing is the most qualified profession to enhance its training in digital competencies and lead technological projects."
- Boost to research: "nursing research would be promoted through the analysis of clinical data, allowing evidence to be generated from practice."
- Strengthening the profession: the EESI role would help to "revalue the nursing profession as a key agent in the digital transformation of health." The aim is for nurses to lead technological change, "(that we) do not just follow it."
- Patient benefits: "care plans and health education, monitoring of care plans," and the promotion of "active patient participation in their care process" are mentioned.

Barriers

The experts' ratings in this section were the most varied (4.4/5). Although the majority continue to identify significant obstacles, one expert is optimistic, noting that "all the classically identified barriers are being progressively addressed, which creates a more favorable and realistic scenario for the effective implementation of nursing informaticians' "role," while the others refer to these previously identified barriers:

- Lack of recognition and regulatory framework: the "absence of official recognition of the role" and the lack of a "regulatory framework and defined policies" are crucial.
- Training and digital literacy: the "scarce specific training at the national level (and a) low level of digital literacy in the nursing community" are mentioned. One expert indicates that "the main barrier is the nursing professionals themselves, due to a lack of time and a culture of digital competencies."
- Resistance to change and organizational culture: "resistance to change from health care professionals accustomed to more traditional work models," and the "lack of clinical leadership from nurses who are experts in information systems" are relevant.
- Resources and infrastructure: "scarce economic, technological, and human resources" and "difficulties in systems integration and terminological standardization" are impediments.

Main Findings

This study reveals a significant dichotomy between the internationally recognized role of the nursing informaticians and their unrecognized role within the Spanish health care system. Through a scoping review, the international evidence has been synthesized, delineating a clear framework of competencies, training models, and benefits associated with this specialized role. Second, the expert-validated gap analysis confirmed that this framework is not only relevant because of its benefits but also essential for the Spanish context nowadays. Barriers that impede its implementation were also identified. The consensus among experts (4.7/5 for benefits and

XSL•FO
RenderX

competencies) underscores a professional and academic mandate to bridge this gap.

Findings articulate 6 core competencies for the nursing informaticians: information management, cybersecurity and patient safety, evaluation and development of clinical information systems, leadership and coordination of digital tools, implementation of new technologies and specialized applications, and education and digitalization in health. These are more than technical skills, as they represent functions such as empowering nurses to act as the central professionals between clinical practice, information technology, and organizational strategy [3,29]. The strong validation by Spanish experts (4.7/5) confirms their applicability and designates a direction for future educational and professional development programs regarding this role.

Discussion

Comparison With Spanish Legal Framework

The status of NI in Spain has proven to be distanced from that of countries such as the United States, Canada, and Australia, where professional associations like the American Medical Informatics Association and the Healthcare Information and Management Systems Society have led the integration of nursing informaticians as those responsible for driving digital transformation [2,8,12,23,25]. A critical analysis of the Spanish legal framework reveals the structural nature of this gap. While international nursing informaticians possess advanced competencies in systems design, cybersecurity, and data leadership, the current regulation of the nursing profession in Spain—specifically Order CIN/2134/2008, which regulates the nursing degree [54], and Royal Decree 954/2015 on nursing prescription [55]—limits digital competencies to the user level.

Both regulations solely and explicitly define the digital competency of nurses in Spain as "applying technologies and information systems" [54,55]. This creates a dichotomy: the legislation exclusively restricts nurses to using existing tools, whereas the health care system increasingly demands qualified specialists to evaluate, design, and lead the implementation of new tools. This restriction within the legal framework illustrates why Spanish nursing staff often feel insufficiently prepared for the digitized clinical environment, echoing findings from Australia [13,49].

Frameworks for Transformation and Cultural Change

A proposed conceptual framework as a driver for change could be the Technology Informatics Guiding Education Reform, with the intent of moving from basic computer literacy toward information management and innovation leadership. The progression of these competencies would reflect the Data-Information-Knowledge-Wisdom model, in which nursing informaticians in Spain would guide digital transformation by using health information and resources to create solutions adapted to the Spanish context.

Overcoming these barriers requires a deliberate and structured strategy, similar to that already achieved by other international pioneers. The emphasis placed by the experts consulted in this study on the "lack of a digital literacy culture" and "resistance from the professionals themselves" points to the need for a cultural shift. Technical training must be accompanied by an evolution of the organizational culture that values data-driven care and nursing leadership in technology.

Implications for Practice, Policy, and Future Research

The findings of this study have significant implications: hospital and health care managers can use the validated competency framework from this study to formally introduce the role requirements. Providing nurses with specialized training and empowering them to lead improvement projects related to information systems or the implementation of new digital tools could potentially create momentum and demonstrate the value of the role so that they are not only technical but also strategic for making nursing care visible [17,26,42,51].

Results suggest a call to action for policymakers and regulatory bodies in Spain, such as the Ministry of Health and National Agency for Quality Assessment and Accreditation, to integrate nursing informaticians' competencies into nursing curricula. This could begin with undergraduate introductions and extend to interdisciplinary master's programs, as suggested by the experts. Collaboration among academia, professional associations, and technology companies is essential to ensure that this training is relevant, practical, and aligned with the needs of the health care system.

Longitudinal studies are needed to evaluate the impact of pilot training programs on nursing competencies. Further research should also focus on developing and validating a standardized instrument to assess NI competencies specifically tailored to the Spanish health care context.

Limitations

This study has several limitations that should be acknowledged. First, the search was limited to studies published in English, Spanish, and Portuguese, which may have excluded relevant literature in other languages. The manuscript has been carefully reviewed by a native English speaker, although some phrasing or constructs may still reflect the linguistic influences of the researchers' native language. Second, the search of gray literature may not have captured all relevant institutional documents or unpublished curricula. Third, the expert panel was selected through purposive sampling to ensure richness of data. Although thematic saturation was reached, the sample was limited to 10 participants. Furthermore, a potential selection bias exists due to the voluntary nature of the recruitment (open call); the experts may possess a baseline "pro-technology" attitude, which could have influenced the highly positive ratings compared to what might be observed in a generalist nursing population. Fourth, the protocol for this scoping review was not prospectively registered in a public repository such as PROSPERO (International Prospective Register of Systematic Reviews). However, the study was conducted following a detailed internal protocol developed by the authors following the PRISMA-ScR and Joanna Briggs Institute guidelines. Finally, a potential publication bias in the literature was spotted, where successful implementations of NI are more likely to be reported than failures. This could skew the international perspective. Future research should address the operational and

XSL•FO
RenderX

budgetary requirements needed to change the organizational governance model for implementing the nursing informaticians' role.

Conclusions

This 2-phase study provides a comprehensive and critical diagnosis of the situation of NI and their role in Spain. It revealed a gap between the nation's current reality and the established international standard. The lack of a conceptual framework, specialized university training, and official recognition for the nursing informaticians' role are the principal barriers preventing nursing informaticians from leading the digital transformation of health care.

The international literature findings were validated by national experts, creating an actionable roadmap. The identified competencies offer a robust foundation for designing educational programs. The successful training models from other countries provide a blueprint for their implementation. The experts' high level of agreement was unequivocal: the nursing informaticians' role is imperative for improving patient safety, optimizing system efficiency, and furthering the development of NI as a scientific discipline in Spain.

Challenges are significant, although the pathway forward is clear. This research serves as a foundational call to action for policymakers, academic institutions, and health care leaders: building regulatory, educational, and organizational infrastructure is needed to empower a new generation of nursing leaders equipped to lead the future of digital health in Spain.

Acknowledgments

The authors would like to acknowledge the experts who participated in the gap analysis for their valuable time and insights. This study is part of the doctoral thesis of Adrián Marco-Moyano, led by Dr Manuel Lillo-Crespo, within the research line "Innovation and Improvement in Health Care" (University of Alicante). The authors used Gemini exclusively for English language editing and proofreading. No artificial intelligence tools were used to create content, data, or references. The authors created, drafted, and verified all aspects of this manuscript and take full accountability for its accuracy and integrity.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Data Availability

The data extracted and analyzed during the scoping review are available from the corresponding author upon reasonable request. The individual responses from the experts are not publicly available to protect participant privacy.

Authors' Contributions

AMM conceived the study and its design. MLC and AMM conducted the literature search, screening, and data extraction. PVR participated in the data extraction and adequacy due to her technological background. MLC and AMM developed the questionnaire and the gap analysis with the experts. All authors drafted the manuscript, critically revised it for intellectual content, and approved the final version for publication.

Conflicts of Interest

Abstract

Background: Nurses are pivotal as end users and implementers of digital mental health interventions (DMHIs). However, the successful translation of efficacious DMHIs into sustainable nursing practice is hindered by multifaceted implementation challenges.

Objective: This study aimed to systematically map and analyze the evolving research landscape of nurse-involved DMHIs to determine if a paradigm shift from efficacy testing to implementation science is occurring and characterize the methodological and thematic trends associated with this shift.

Methods: We conducted a scoping review integrated with a bibliometric analysis following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines. A comprehensive search of the Web of Science Core Collection, Scopus, and PubMed databases (January 2020 to April 2026) yielded 1014 eligible primary research studies. Studies were classified as “efficacy/effectiveness” or “implementation” research using a validated framework. We analyzed temporal trends and methodological designs and performed co-word thematic mapping.

Results: Implementation research constituted the largest proportion of clearly classified studies (327/470, 69.6%), exceeding efficacy research (143/470, 30.4%). Implementation research demonstrated a significant growth trajectory from 2020 to 2025 (β=8.63 articles per year; *P*=.003), surpassing efficacy research in 2022. Implementation studies used more mixed methods (105/327, 32.1% vs 7/143, 4.9%; *P*<.001) and qualitative designs (92/327, 28.1% vs 2/143, 1.4%; *P*<.001). Thematic analysis revealed “nursing workflow integration” and “nurse-led implementation” as emerging motor themes.

Conclusions: This review provides robust evidence of an accelerating turn to implementation in digital mental health research in nursing. The field is moving beyond internal validity toward real-world implementation. Future efforts should focus on implementation-ready digital tools and embedding implementation science competencies into nursing education.

Introduction

The integration of digital mental health interventions (DMHIs) into routine nursing practice represents both an opportunity and a challenge for contemporary health care systems [1-3]. Nurses, as the largest group of health care professionals worldwide, are uniquely positioned to serve as frontline implementers, coordinators, and sustainers of DMHIs across diverse clinical settings [4,5]. However, despite growing evidence of DMHI efficacy from over a decade of randomized controlled trials [6,7], their real-world implementation in nursing practice remains limited, creating what has been termed the “implementation-to-practice gap” in digital mental health [8,9].

Recent systematic reviews have consistently identified nurse-specific barriers to DMHI adoption, including workflow disruption, inadequate training, and concerns about increased workload [10,11]. A 2020 mixed methods study by Bourla et al [12] found that although over 70% of student nurses reported willingness to adopt digital mental health technologies in clinical practice, more than 60% voiced worries that such tools could damage the therapeutic relationship, indicating that the readiness

XSL•FO
RenderX

of future nursing practitioners to implement DMHIs remains insufficient. Concurrently, the global nursing shortage, exacerbated by the COVID-19 pandemic, has intensified interest in digital solutions that can extend the reach of mental health services [13,14].

Implementation science offers conceptual frameworks and methodological approaches specifically designed to address these implementation challenges [15,16]. Frameworks such as the reach, effectiveness, adoption, implementation, and maintenance framework [17] and the Consolidated Framework for Implementation Research [18] shift the research focus from questions of efficacy ("Does it work under ideal conditions?") to questions of implementation ("How can nurses successfully integrate this into their workflow?"). While calls for greater attention to implementation science in nursing digital health research have increased [19,20], the extent to which the published literature reflects this methodological paradigm shift remains empirically unexamined.

To inform the development of more implementable digital tools and effective support strategies for nurses, this scoping review and bibliometric analysis systematically mapped the published literature from 2020 to 2026. We sought to determine whether nurse-involved DMHI research is indeed undergoing this critical implementation turn. Our specific objectives were to (1) quantify the prevalence of implementation-focused research vs efficacy research, (2) analyze temporal trends in this paradigm adoption, (3) compare the methodological approaches characterizing each paradigm, and (4) identify the key thematic foci and their evolution within the nursing DMHI literature. A conservative keyword-based classification strategy was used to prioritize specificity, providing a lower-bound estimate of implementation research prevalence.

Methods

Study Design

This study was conducted as a scoping review incorporating a bibliometric analysis in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) statement [21]. The review protocol was not preregistered. Our primary objective was to systematically map and characterize the published literature on nurse-involved DMHIs from 2020 to 2026. The completed PRISMA-ScR checklist is provided in Checklist 1.

Data Source and Search Strategy

Data were retrieved from 3 electronic databases on April 15, 2026: Web of Science Core Collection, Scopus, and PubMed. The search was limited to peer-reviewed journal articles published in English between January 1, 2020, and April 15, 2026. The search strategy combined terms related to three conceptual domains: (1) digital interventions [22,23], (2) mental health conditions [3], and (3) nursing involvement and research paradigms [4,8]. The complete search strategy for each database is provided in Multimedia Appendix 1.

Inclusion and Exclusion Criteria

Articles were included if they met all of the following criteria: (1) focused primarily on a digital intervention targeting mental health conditions; (2) involved nursing roles (nurse-led, nurse-delivered, or nurse-involved implementation); (3) reported original empirical research with human participants; (4) were published in English in peer-reviewed journals; and (5) were published between January 1, 2020, and April 15, 2026. We excluded review articles, study protocols, commentaries, editorials, theoretical papers, and studies in which nursing involvement was peripheral.

Article Classification and Validation

Publications were classified using a multistage process informed by implementation science frameworks [18,24]. Implementation research was defined by a focus on real-world adoption and implementation outcomes in nursing contexts [25], and efficacy and effectiveness research was defined by a focus on clinical outcomes under controlled conditions. A conservative keyword-based classification strategy was used to prioritize specificity, providing a lower-bound estimate of implementation research prevalence. Classification followed 3 stages: automated keyword screening, manual verification, and validation against a consensus standard (κ=0.73, 95% CI 0.60-0.86).

Data Extraction and Quality Assessment

Two reviewers independently extracted data from each included study using a standardized form. Extracted items included first author, publication year, country, study design, sample size, research paradigm (implementation vs efficacy or effectiveness), theoretical framework used, implementation outcomes measured (if applicable), and key themes. Disagreements were resolved through discussion or consultation with a third reviewer. Quality assessment was not performed as this was a scoping review focused on mapping the literature rather than critically appraising evidence quality [21].

Statistical and Bibliometric Analysis

Descriptive statistics summarized publication characteristics. Proportions with 95% CIs were calculated using the Wilson score method. Temporal trends were analyzed using linear regression. Methodological differences between research paradigms were examined using chi-square tests. Co-word analysis and thematic mapping were conducted using the *bibliometrix* package in R (version 4.2; R Foundation for Statistical Computing) [26].

Ethical Considerations

This study involved analysis of publicly available published literature and did not require ethics approval.

Results

Study Selection and Characteristics

Our search identified 1737 records across 3 databases (Scopus: n=1183, 68.1%; Web of Science: n=431, 24.8%; PubMed: n=123, 7.1%). To ensure a conservative estimate of unique publications, we performed deduplication using both digital object identifier (DOI) and title. Of the 1737 identified records,

XSL•FO
RenderX

DOI-based deduplication removed 337 (19.4%) duplicates (resulting in n=1400, 80.6% of records), and subsequent title-based deduplication identified an additional 386 (22.2%) duplicate records with inconsistent or missing DOI assignments across databases. This 2-stage approach yielded 1014 unique records (Figure 1). All 1014 records met the inclusion criteria for original empirical research on nurse-involved DMHIs published in English between 2020 and 2026.

The final sample included studies from 44 countries. The largest contributions came from the United States (373/1014, 36.8%), the United Kingdom (161/1014, 15.9%), Australia (110/1014, 10.8%), and China (83/1014, 8.2%). The mean sample size of primary studies was 162 (SD 241) participants.

Across all 1014 included studies, randomized controlled trials represented the most common study design (n=303, 29.9%). Observational designs followed as the second most frequent category (n=129, 12.7%), followed by mixed methods research (n=106, 10.5%). Feasibility and pilot studies and qualitative studies each comprised 7.1% (n=72) of the studies, whereas process evaluation designs were the least prevalent (n=44, 4.3%).

Prevalence of Research Paradigms

For research paradigm classification, a conservative keyword coding approach left 53.6% (544/1014) of the total studies with an ambiguous categorization that could not be clearly assigned to either implementation- or efficacy-focused work. Among the remaining 470 clearly classified studies, implementation-focused research constituted the dominant paradigm at 69.6% (n=327), whereas efficacy and effectiveness research made up the remaining 30.4% (n=143). All mixed or hybrid methodological studies were subsumed within the implementation research grouping in line with standard implementation science classification frameworks [27]. The implementation-to-efficacy study ratio was calculated at 2.29:1, demonstrating a preponderance of implementation research within the clearly classified sample.

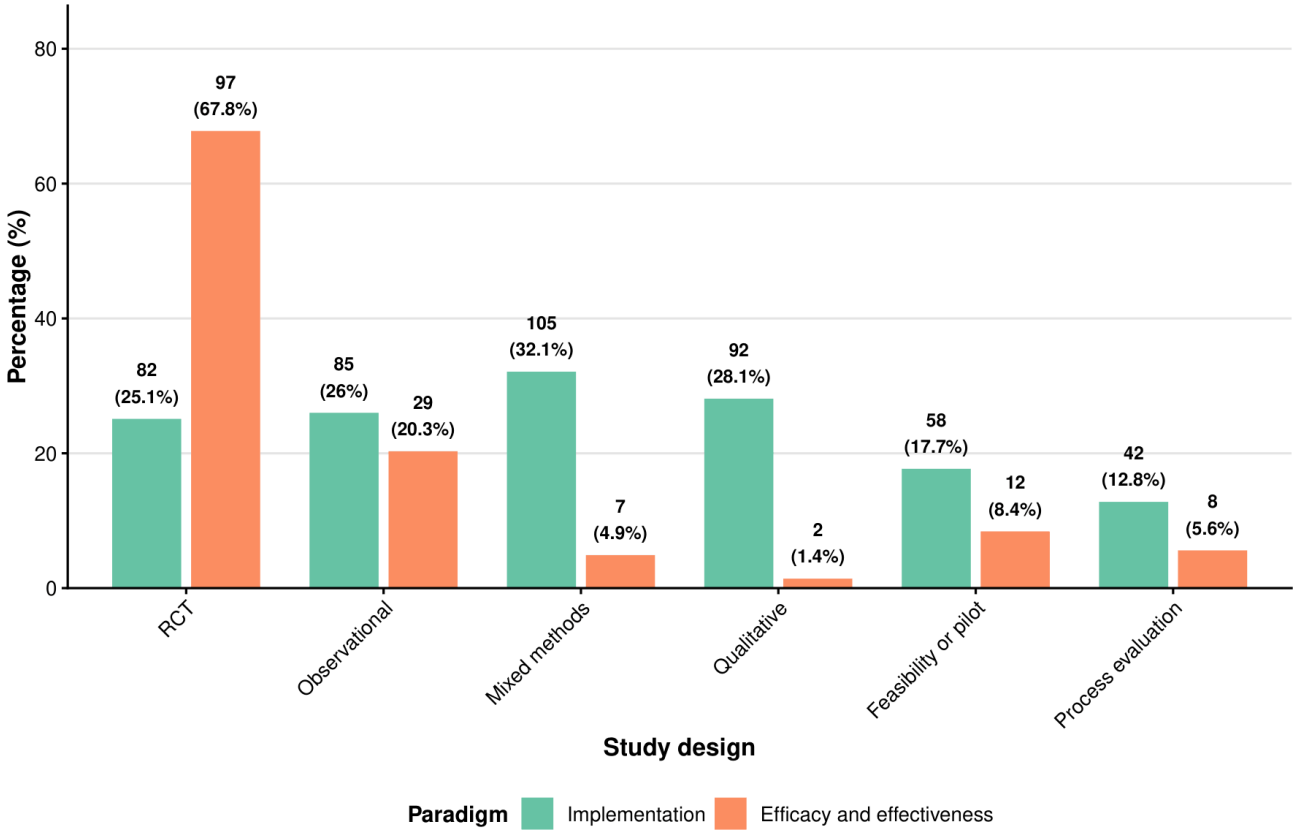
Temporal Trends in Paradigm Adoption

Publication volume demonstrated substantial growth from 2020 to 2025 (Figure 2), increasing from 102 articles in 2020 to 247 in 2025 (142% increase). Linear regression analysis revealed a significant positive trend in implementation research from 2020 to 2025 (β=8.63 articles per year, 95% CI 5.21-12.05; *P*=.003; R^2=0.91). Implementation research studies outnumbered efficacy research studies in 2022 (47 implementation-related articles vs 15 efficacy or effectiveness articles) and retained this predominance in subsequent years, peaking at 74 articles in 2025. Efficacy and effectiveness research demonstrated no statistically significant growth across the study period (β=1.8 articles per year; *P*=.48). The lower count in 2026 (21 implementation articles) reflects incomplete year data and was excluded from trend analysis.

Figure 2. Annual publication trends by research paradigm (2020-2025). Implementation research demonstrated a significant growth trajectory, increasing from 32 articles in 2020 to 74 in 2025, surpassing efficacy research in 2022 (47 vs 15). Linear regression analysis (2020-2025) revealed a β value of 8.63 articles per year (95% CI 5.21-12.05; *P*=.003; R^2=0.91). Efficacy and effectiveness research showed no significant growth (β=1.8; *P*=.48). The year 2026 was excluded due to incomplete data.

Methodological Divergence Between Paradigms

Analysis of studies with unambiguous classification revealed substantial methodological divergence (Table 1 and Figure 3). Implementation studies used significantly more mixed methods designs (105/327, 32.1% vs 7/143, 4.9%; χ^2_5=32.4; *P*<.001) and qualitative approaches (92/327, 28.1% vs 2/143, 1.4%; χ^2_5=41.2; *P*<.001) compared to efficacy and effectiveness studies. In contrast, efficacy research remained predominantly reliant on randomized controlled trials compared to implementation studies (97/143, 67.8% vs 82/327, 25.1%, respectively; χ^2_5=24.8; *P*<.001).



XSL•FO

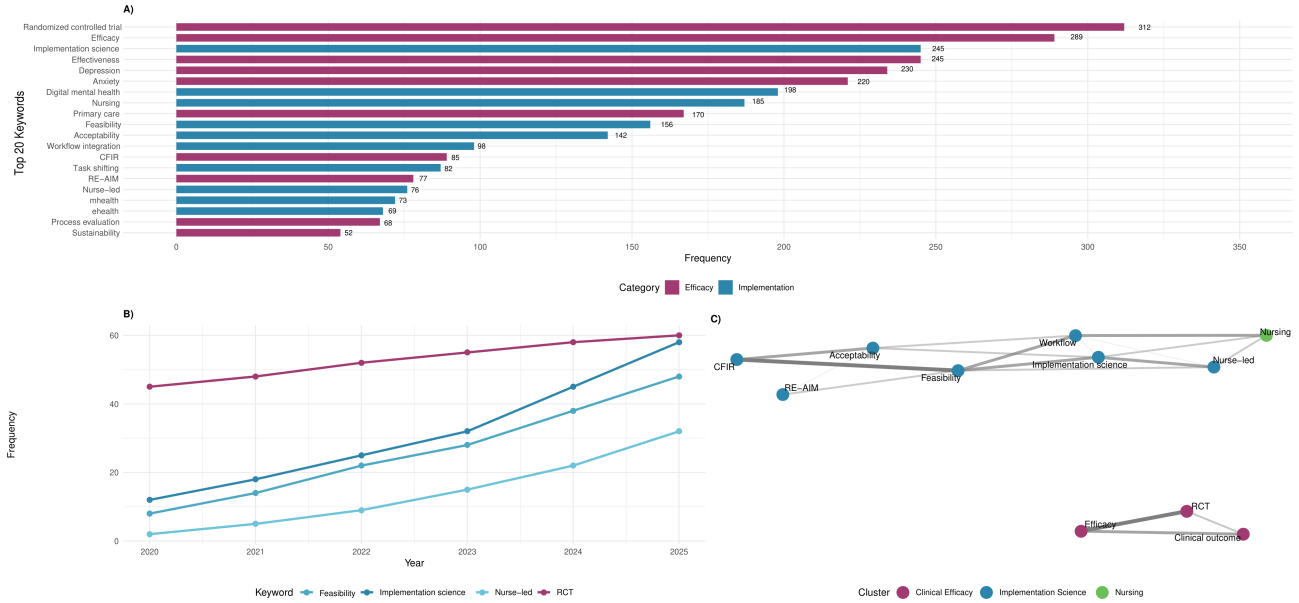
Table . Methodological approaches across research paradigms (n=470 studies with unambiguous classification).[a]

Study design	Implementation research (n=327), n (%)	Efficacy and effectiveness research (n=143), n (%)	Chi-square (*df*)	*P* value
RCT[b]	82 (25.1)	97 (67.8)	24.8 (5)	<.001
Observational	85 (26.0)	29 (20.3)	1.8 (5)	.41
Mixed methods	105 (32.1)	7 (4.9)	32.4 (5)	<.001
Qualitative	92 (28.1)	2 (1.4)	41.2 (5)	<.001
Feasibility or pilot	58 (17.7)	12 (8.4)	2.3 (5)	.32
Process evaluation	42 (12.8)	8 (5.6)	3.9 (5)	.14

[a]Percentages exceed 100% because studies may use multiple designs. Chi-square tests compare implementation vs efficacy and effectiveness research.
[b]RCT: randomized controlled trial.

Figure 3. Methodological approaches across research paradigms (n=470 studies with unambiguous classification). Implementation research used significantly more mixed methods (105/327, 32.1% vs 7/143, 4.9%; *P*<.001) and qualitative designs (92/327, 28.1% vs 2/143, 1.4%; *P*<.001) compared to efficacy and effectiveness research, which remained predominantly reliant on randomized controlled trials compared to implementation studies (97/143, 67.8% vs 82/327, 25.1%, respectively; *P*<.001). RCT: randomized controlled trial.



Thematic Evolution and Nursing-Specific Patterns

Co-word analysis of keywords from all 1014 publications revealed a clear thematic evolution toward implementation science (Figure 4). Implementation-focused constructs including "implementation science," "nursing workflow," "task-shifting," and "nurse-led implementation" emerged as motor themes characterized by high centrality and density. Nursing-specific implementation barriers such as "time constraints," "training needs," and "workflow integration" showed increasing prominence in recent publications (2024 - 2025). Notably, implementation-related keywords showed the highest annual growth rate among all thematic categories (β=2.1 appearances per year; *P*=.008).

XSL•FO
RenderX

Figure 4. Thematic evolution in nurse-involved digital mental health research (N=1014). (A) Bar chart of the top 20 most frequently occurring keywords across all the included studies. Implementation-related keywords (blue) dominate the top ranks, with "randomized controlled trial" (n=312) and "efficacy" (n=289) being the most frequent efficacy-related terms. (B) Annual trends of the top 10 keywords (2020-2025), demonstrating increasing prominence of implementation-related terms ("implementation science," "feasibility," and "nurse-led"), whereas efficacy-related terms ("RCT") remained stable. The year 2026 was excluded due to incomplete data. (C) Keyword co-occurrence network showing three distinct clusters: (1) implementation science (blue; centrality=0.85), (2) clinical efficacy research (purple; centrality=0.32), and (3) nursing workflow integration (green; centrality=0.68). Implementation science emerged as a motor theme with high centrality and density.

Discussion

Principal Findings

Our bibliometric analysis of 1014 nurse-involved DMHI studies provides robust empirical evidence of a decisive paradigm shift toward implementation science. Three convergent lines of evidence support this conclusion. First, implementation research constituted the largest proportion of clearly classified studies (327/470, 69.6%), exceeding traditional efficacy research (143/470, 30.4%). Second, implementation research demonstrated a significant annual growth rate of 8.63 articles per year from 2020 to 2025 (P=.003; R^2=0.91), surpassing efficacy research in 2022. Third, fundamental methodological differences characterize these paradigms, with implementation studies using substantially more mixed methods (105/327, 32.1% vs 7/143, 4.9%) and qualitative designs (92/327, 28.1% vs 2/143, 1.4%).

Comparison With Existing Literature

Our findings align with broader trends in implementation science but extend them to the specific context of nursing digital health [28,29]. Previous research has documented increasing attention to implementation science in health care generally [30], but our study is the first to quantify this shift specifically in nurse-involved DMHI research using a multi-database bibliometric approach. The methodological divergence we observed—with implementation studies favoring mixed methods approaches—reflects the complex, context-dependent nature of implementation challenges in nursing practice [27].

Recent studies have begun to identify effective nurse-specific implementation strategies. Targeted, blended training combining online learning and in-person coaching markedly elevates nurses' adoption of digital mental health tools, with intervention groups demonstrating more than double the uptake relative to untrained control staff [31]. Similarly, research confirms that "implementation champions" drive long-term sustainability; grassroots nurse-led digital interventions maintain stable clinical use far longer than institution-mandated top-down rollouts [32].

Implications for Nursing Practice

The documented shift has direct implications for creating more nurse-friendly digital health ecosystems.

First, for digital health developers, our findings underscore the necessity of "implementation by design." DMHI development must move beyond user experience for patients to include clinician experience for nurses, explicitly considering workflow integration, time burden, and interoperability with clinical systems from the earliest stages [22,23].

Second, for nursing informatics leadership, chief nursing informatics officers and other leaders must advocate for and allocate resources toward implementation infrastructure. This includes dedicated time for nurse training and adaptation, the creation of role-specific implementation playbooks, and the evaluation of DMHIs based on implementation outcomes (eg, adoption, feasibility, and sustainability) alongside clinical outcomes [33].

Third, for education and training, nursing curricula and continuing professional development must evolve to build digital health implementation competency. This includes skills in evaluating digital tools for implementability, leading practice change, and using data from DMHIs to inform care—a core component of modern nursing informatics literacy [34,35].

XSL•FO
RenderX

Future Directions for Nursing Research

Our findings suggest several directions for future nursing research. First, there is a need for more hybrid effectiveness-implementation designs that simultaneously examine clinical outcomes and implementation processes [27]. Second, research should explore nurse-specific implementation strategies such as tailored training programs and workflow integration tools [36]. Third, future studies should examine how implementation outcomes vary across nursing roles and settings [37]. Finally, given the geographic concentration of research in high-income countries, there is an urgent need for implementation research in low- and middle-income settings, where nurses often serve as the primary mental health care providers [38].

Strengths and Limitations

Strengths of this study include its comprehensive multi-database search strategy (Web of Science, Scopus, and PubMed), rigorous classification system with validation (κ=0.73), updated search up to April 2026, and integration of multiple bibliometric techniques, analyzing 1014 eligible studies.

Several limitations warrant acknowledgment. First, reliance on title and abstract text for initial classification may have misclassified some studies, although manual verification and consensus validation mitigated this risk. Our conservative classification strategy prioritized specificity, resulting in a higher proportion of unclear classifications (544/1014, 53.6%); this provides a lower-bound estimate of implementation research prevalence. Second, the exclusion of non–English-language publications introduces language bias, potentially missing relevant research from non–English-speaking countries. Third, we did not include CINAHL due to institutional access limitations, which may have underrepresented nursing-specific literature. Future reviews should include this database. Fourth, the rapid evolution of digital health technologies means that findings from older studies (2020-2022) may not fully reflect current capabilities, although our temporal trend analysis addresses changing patterns over time. Fifth, the lack of quality assessment, consistent with scoping review methodology, means that we cannot comment on the methodological rigor of the included studies.

Conclusions

This scoping review and bibliometric analysis documents a decisive and accelerating paradigm shift toward implementation science in nurse-involved DMHI research. Implementation research now constitutes the dominant paradigm (327/1014, 32.2% vs 143/1014, 14.1% for efficacy research) and demonstrated a significant annual growth rate of 8.63 articles per year from 2020 to 2025 (P=.003; R^2=0.91), surpassing efficacy research in 2022. The field is expanding beyond a primary focus on internal validity to systematically investigate the complex determinants and processes of real-world implementation in nursing contexts.

Acknowledgments

The authors thank the librarians at Shanghai Jiao Tong University for assistance with database searching.

SY conceived the study, drafted the manuscript and collated table data. SY, LQ, and HW completed all statistical and bibliometric analyses. All authors revised the manuscript and approved the final version.

Abstract

Background: Artificial intelligence (AI)–based nursing interventions are increasingly being used to manage chronic illnesses; however, their definitive impact on clinical outcomes remains inconclusive, necessitating a comprehensive evidence synthesis.

Objective: This umbrella review aimed to synthesize the evidence regarding the effectiveness of AI-based nursing interventions for chronic illness care and their subsequent impact on health care outcomes in clinical settings.

Methods: We conducted an umbrella review and prospectively registered the protocol. A systematic search of 5 electronic databases (PubMed, CINAHL, Cochrane Library, Scopus, and Web of Science) was performed to identify systematic reviews and meta-analyses published in English between 2021 and 2025. The methodological quality of the included studies was evaluated using the Joanna Briggs Institute (JBI) Critical Appraisal Checklist.

Results: Eight high-quality systematic reviews were included, with machine learning identified as the predominant technology. Three primary outcome domains emerged: predictive, psychosocial, and hospital utilization. Due to measurement heterogeneity, the results were synthesized narratively. Our findings demonstrated that AI-based nursing interventions are effective in predicting adverse clinical events, unplanned hospital utilization, and health care costs. However, evidence regarding psychosocial outcomes remains insufficient.

Conclusions: This review provides systematic evidence supporting the utility of AI in chronic illness management, particularly for improving predictive and utilization outcomes. These findings offer actionable insights for nursing leaders to integrate AI into clinical practice and education. Future research should prioritize rigorous empirical designs to further strengthen the evidence base for AI-driven nursing care.

KEYWORDS

artificial intelligence; chronic illness; nursing intervention; systematic review; umbrella review

Introduction

Background

In recent years, the evolution of artificial intelligence (AI) has led to major transformations in the nursing domain. The World Health Organization (WHO) announced that health care systems should use AI technologies for patient-centered and continuous care [1]. The International Council of Nurses (ICN) has highlighted that the adoption of AI is an innovative approach to health care and a potentially beneficial tool for providing nursing care to patients to enhance global health and wellness [2]. Ultimately, AI technologies adopted in health care systems have been integrated into nursing research, practice, and health care systems.

Globally, chronic illnesses have been a serious public health problem for decades. Referred to as “the Silent Pandemic,” chronic illnesses account for approximately 74% of global deaths and pose challenges to global health systems and the economy [1]. Individuals with chronic illnesses experience multiple comorbidities, require continuous care from nurses, and experience recurrent planned or unplanned hospital visits. Evidence from nursing research has shown that interventions by nursing professionals improve chronic illness care. Nurses are key health care professionals who provide patient-centered and effective coordinated care to improve chronic illness outcomes [3,4].

With the evolution of AI in nursing, extensive efforts have been made to apply AI technologies and algorithms. Specific AI techniques in nursing include machine learning (ML), deep learning (DL), robotics, decision support systems, and natural

XSL•FO
RenderX

language processing [5,6]. AI algorithms are computational procedures that enable computers to execute specific tasks by following predefined rules and processing data. Common AI algorithms include decision trees, logistic regression, random forests, neural networks, and Naïve Bayes [7]. AI techniques and algorithms have been used to predict patient conditions and risks, support disease diagnosis, and provide personalized care [8,9].

Several reviews have examined AI-based health care interventions and their impact on patient care [10-12]. Previous evidence has also explored the application of AI in nursing research, practice, and education [5,13,14]. In addition, reviews focusing on AI-based nursing interventions for chronic illness care have been conducted [15-17]. However, the findings regarding the effectiveness of AI-based nursing interventions remain inconsistent because of varied outcome measures and a lack of consensus regarding their clinical impact. This evidence gap may hinder the advancement and implementation of AI-supported nursing care for chronic illnesses. Therefore, a comprehensive synthesis of current evidence is needed. Accordingly, this umbrella review aimed to identify and evaluate the effectiveness of AI-based nursing interventions for chronic illnesses and their impact on health care outcomes in clinical settings.

Objective

This study addressed two research aims: (1) to identify nursing interventions in health care settings that apply AI in caring for chronic illnesses to influence health care outcomes and (2) to synthesize and evaluate the impacts of AI-based nursing interventions on chronic illnesses.

Methods

Study Design

This study followed the umbrella review methodology developed using the Joanna Briggs Institute (JBI) guidelines [18]. An umbrella review is an approach that compiles the best evidence from existing published systematic reviews (SRs) to obtain a single comprehensive review [18]. This umbrella review methodology is useful for aggregating and expanding recent issues and for highlighting synthesized evidence for future directions in health care research [18]. This umbrella review was conducted using the PICO (Population, Intervention, Comparison, and Outcome) framework to define the eligibility criteria and guide paper selection [19]. The review process adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (see Checklist 1). The PICO framework was considered appropriate because the review sought to capture a broad range of evidence regarding AI-based nursing interventions across diverse intervention designs, health care settings, and patient outcomes. This review has been registered with the PROSPERO (International Prospective Register of Systematic Reviews) database. No institutional review board approval was required because no humans were included in the study.

Search Strategy

Five electronic bibliographic databases (CINAHL, Cochrane Library, PubMed, Scopus, and Web of Science) were searched to identify relevant studies. The complete search strategy for each database, including Boolean operators and keyword combinations, was developed in consultation with the research team and is provided in Table S1 of Multimedia Appendix 1 to enhance reproducibility.

The following keywords and Medical Subject Headings were used with Boolean operators (AND and OR): (“artificial intelligence” OR “AI” OR “machine learning” OR “technology”), (“systematic review” OR “meta-analysis”), and (“chronic” OR “chronic disease” OR “chronic illness”) or (“nurse” OR “nursing”). Several additional search terms were used: “prediction” or “effectiveness” or “health outcome” or “nursing research.” To capture the most current evidence regarding the rapid evolution of AI in nursing, we limited our selection to SRs published within the past 5 years. Therefore, SRs with and without meta-analyses published between January 2021 and December 2025 were included in this study. This time frame was selected because AI technologies in nursing and health care have rapidly evolved in recent years, particularly following the increased implementation of ML, conversational agents, and predictive analytics in clinical practice after 2020. Restricting this review to recent SRs enabled the inclusion of the most contemporary evidence reflecting current AI capabilities, health care infrastructure, and nursing practices. However, we acknowledge that this restriction may have excluded earlier relevant evidence and potentially introduced selection bias. Articles available ahead of print publications or as online-first publications were also included. The initial search was conducted on December 1, 2025, and a confirmatory search was conducted on February 28, 2026, to identify potentially eligible studies.

Inclusion and Exclusion Criteria

Textbox 1 shows the inclusion and exclusion criteria. Based on the PICO framework, the Population (P) included patients with chronic illnesses (eg, diabetes, hypertension, and chronic kidney disease) who received nursing care services; the Intervention (I) was defined as the integration of AI-based technologies into nursing interventions in health care settings. The Comparison (C) included the usual care, control groups, or non–AI-based interventions. The Outcome (O) included quantitative patient outcomes. The eligible studies were SRs with or without meta-analysis that included primary empirical studies such as cross-sectional studies, quasi-experimental studies, and randomized controlled trials (RCTs).

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Quantitative systematic review or systematic review with meta-analysis focused on nursing interventions (nurse-led or nurses involved and nursing scholars conducted) that explicitly applied artificial intelligence (AI)–based technologies to chronic ill patients
- Systematic reviews that targeted chronically ill patients who diagnosed diseases or admitted to hospitals or health care facilities with nursing care services
- Systematic reviews with nursing interventions (nurse-led interventions) that explicitly and strictly applied AI-based technologies to patients who may benefit
- Systematic reviews published in peer-reviewed academic journals
- Systematic reviews synthesized empirical studies as their included primary studies
- Systematic reviews published from January 2021 to December 2025 (included ahead of print)

Exclusion criteria

- Editorials, policy papers, commentaries, or qualitative synthesis or qualitative reviews
- Reviews that did not include patients as participants and did not report patient outcomes
- Reviews that did not use AI-powered health technologies and not mainly delivered by nurses (eg, papers that used clinical decision systems that are not based on AI are excluded)
- Reviews that were published in non–peer-reviewed academic journals
- Reviews that did not focus on nursing or nurses or were not conducted by nursing scholars
- Studies in languages other than English

In this umbrella review, AI-based nursing interventions were operationally defined as nursing-related interventions that incorporated AI technologies to support assessment, clinical decision-making, patient monitoring, communication, education, or care coordination for patients with chronic illnesses. In this review, AI-based nursing interventions refer to those that incorporate AI technologies, such as ML models, predictive analytics, or clinical decision support systems, to support nursing assessment, decision-making, monitoring, or care coordination. These interventions included nurse-led applications implemented directly by nurses or nurse practitioners (NPs), as well as AI-supported systems integrated into nursing workflows within health care settings. Studies were included if AI technologies were integrated into nursing care delivery, nursing assessment, nurse-led chronic disease management, or other nursing-related clinical workflows. However, studies focusing solely on institution-level administrative AI systems without direct relevance to nursing care delivery were excluded. This umbrella review also excluded publications that were not published in English or that indicated the use of generative AI, such as ChatGPT, in manuscript writing.

In this umbrella review, “adverse events” were operationally defined as undesirable clinical outcomes associated with chronic illness progression or health care utilization, including mortality, unplanned hospital readmission, intensive care unit (ICU) admission, and disease-related deterioration. “Complications” referred to disease-related secondary conditions such as neuropathy, nephropathy, retinopathy, or other chronic illness–related sequelae. “Hospital utilization outcomes” included hospital readmissions, emergency department visits, length of hospital stay, and health care–related costs. To improve consistency and interpretability, these terms were used consistently throughout this review.

Study Selection

Two reviewers independently screened the titles, abstracts, and full texts based on the predefined eligibility criteria. Any disagreements regarding study inclusion were resolved through discussion and consensus among all research team members. When consensus could not be reached initially, the final decision was made after a repeated review of the full-text article and methodological criteria. To assess potential double-counting bias, overlap among the included SRs was examined using a citation matrix. The primary studies included in each SR were extracted and compared across reviews to identify overlapping studies and duplicate publications.

Quality Appraisal of Selected SRs

For umbrella reviews, it is recommended to assess the professional and methodological quality of the included SRs using a validated checklist [18,20]. This study used the JBI Critical Appraisal Checklist for SRs [21]. This checklist is recommended for umbrella reviews and provides a structured assessment of the methodological quality of SRs. It was developed to evaluate research methodologies and address the risks of bias in included studies when conducting an umbrella review [20]. Therefore, it was considered appropriate for the methodological approach in this umbrella review. The checklist consists of 11 questions in the following domains: study aim, search strategy, inclusion and exclusion criteria, data selection and extraction, publication bias, and appropriate results. These questions have 4 response options: “yes,” “no,” “unclear,” and “not applicable.” The total sum of responses ranged from 0 to 11; if the answer was “yes,” it was scored as 1; otherwise, it was scored as 0. The JBI checklist does not provide predefined cutoff scores to classify reviews as high, moderate, or low quality. However, high scores indicate high quality and low risk

XSL•FO
RenderX

of methodological bias. The first and second researchers independently evaluated the quality of the 8 selected studies using the checklist.

Data Extraction and Synthesis

In this study, data were extracted by the primary researcher using an Excel data sheet. A standardized Excel-based extraction form was developed prior to data extraction to improve consistency and reproducibility. The form included (1) bibliographic details (authors, types and designs of reviews, authors' nationality, and publication years), (2) aims, (3) number of primary studies used in an SR, (4) details of databases used, (5) quality assessment tools, and (6) study participants. A summary of the types of AI reported in the selected studies, the algorithms used, and the findings of common health care outcomes was also extracted onto another data sheet. The primary researcher extracted the data, and the third researcher verified the extraction.

Due to substantial heterogeneity across the included SRs in terms of AI techniques, intervention characteristics, patient populations, chronic illness types, outcome measurements, and study designs, a quantitative meta-analysis was considered inappropriate. In particular, the included reviews used diverse outcome measures and varying definitions of health care outcomes, which limited the comparability of pooled effect sizes. Therefore, a narrative synthesis approach was adopted to comprehensively summarize and interpret the findings.

Results

General Characteristics of Included Reviews

Figure 1 presents a summary of the search process and study selection outcomes using a PRISMA flow diagram. A total of 541 records were initially identified from the 5 electronic databases. After removing duplicate records (n=190) using EndNote X9 (Clarivate Analytics), 351 unique records remained for screening. Of these, 284 records were excluded during title screening, and 44 records were excluded after abstract screening based on the predefined eligibility criteria. Full-text eligibility assessment was conducted for the remaining 23 reports, and 15 reports were excluded because they did not meet the inclusion and exclusion criteria. Finally, 8 SRs were included in this umbrella review.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram.

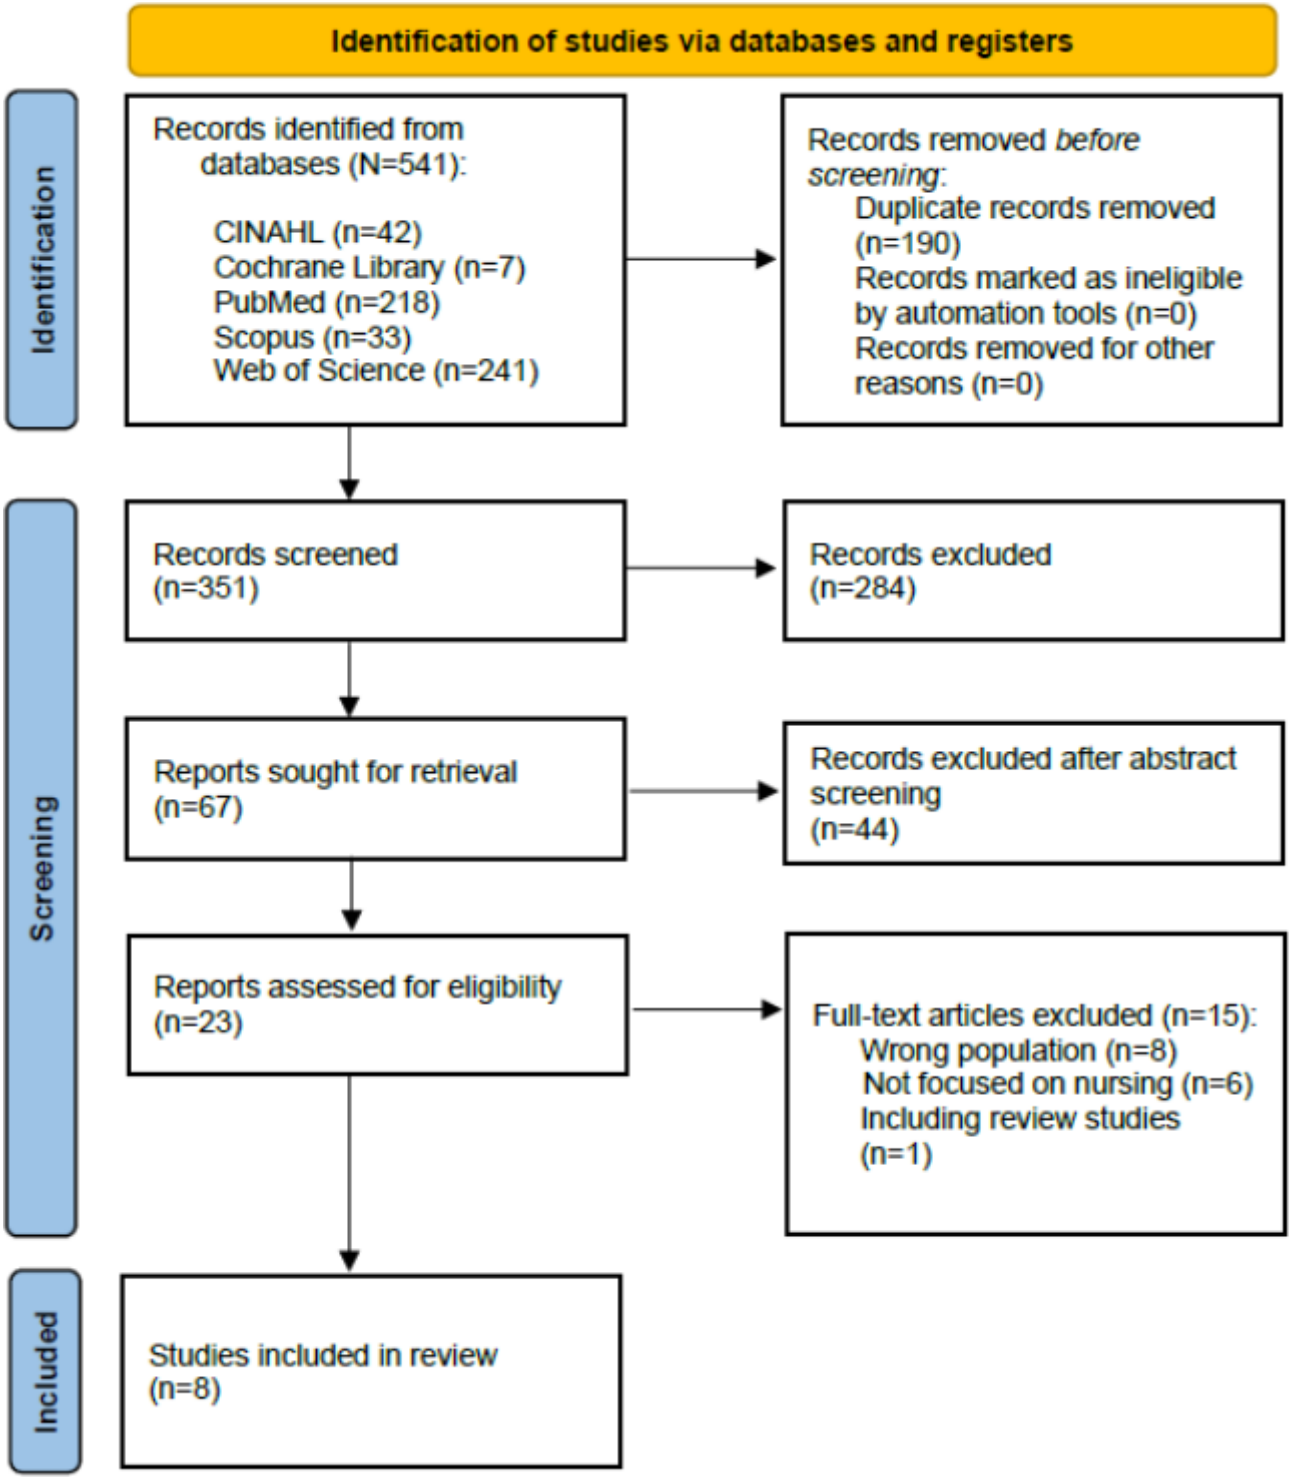

Table 1 presents the general characteristics of the 8 SRs, including the study aim, number of primary studies included, review methods, sample sizes, and year of publication. The 8 SRs were published between 2021 and 2025 [4,15-17,22-25]. These studies investigated the impact of AI-based nursing interventions on patients with chronic illnesses and analyzed their health care–related outcomes resulting from the interventions. The 8 included reviews were conducted in China (n=2), the United Kingdom, the United States, Canada, South Korea, Indonesia, and Slovenia (n=1 each), and they all followed the PRISMA guidelines . Three SRs had registered their review protocols with PROSPERO, while the rest did not report any registration. Three SRs included only RCTs [16,22,25]. Among the included SRs, only 1 SR conducted a meta-analysis [17].

The 8 SRs included a total of 150 primary study records. A citation matrix identified 7 overlapping primary studies across the reviews, corresponding to 8 duplicate publications. After accounting for overlap, 142 unique primary studies were represented in this umbrella review (Table S4 in Multimedia Appendix 1). Given the relatively small number of overlapping studies, the risk of double-counting bias was considered limited. Among these, 41 studies were RCTs, and the rest were

XSL•FO
RenderX

quasi-experimental, retrospective cohort, or cross-sectional studies. Each SR included 5 to 65 primary studies published across various continents, such as North and South America, Europe, and Asia, from 2008 to 2024. Although all the SRs were published in English, the primary studies included in the reviews were published in the English, Chinese [17], or Korean [25] languages. These 2 SRs, which included primary studies in languages other than English, used translation and back-translation methods.

Based on the inclusion criteria, the participants were patients aged at least 16 years or older who had at least 1 chronic illness, such as type 2 diabetes mellitus or cancer, had been hospitalized in ICUs, or had visited the emergency department due to their chronic illness. The number of participants in primary studies ranged from 28 to 469,976.

Summary of AI-Based Nursing Interventions in the SRs

Table 2 summarizes the characteristics of AI-based nursing interventions used in the studies. Additionally, Tables S2 and S3 in Multimedia Appendix 1 summarize the characteristics of AI-based nursing interventions used in the studies. Table S2 in Multimedia Appendix 1 provides the number of studies that use different types of AI interventions. All the primary studies clearly reported the utilization of AI techniques and AI algorithms in their nursing interventions. In this study, the AI-based nursing interventions in the reviews were classified as AI techniques [26]. The main AI interventions retrieved from the studies included ML, which was used in all 8 studies, followed by DL, clinical decision support, and natural language processing. The types of AI algorithms used were the decision tree model, logistic regression, neural networks, and Naïve Bayes. Several AI algorithms, such as regressions, Naïve Bayes, and neural networks, were used as prediction models. The most frequently used AI algorithm was logistic regression (used in all 8 SRs). Two SRs reported that chatbots and conversational agents [22,23] were used in their nursing interventions, and 1 SR used real-time voice AI support [25].

[f]ICU: intensive care unit.
[g]IG: intervention group.
[h](–): no effect.
[i]QoL: quality of life.
[j](±): inconclusive and mixed results.
[k]CG: control group.

Most AI-based interventions were led by nurses or NPs [22,24,25] and delivered by nurses or NPs within multidisciplinary health care settings [4,15-17]. These interventions were directly integrated into nursing workflows, including patient monitoring and education, symptom assessment, discharge planning, follow-up, and chronic illness management [4,15-17,22,24]. Some SRs incorporated AI decision support systems and predictive algorithms [16,17,25]; however, these AI technologies were implemented within supporting nursing interventions such as assessment, clinical decision-making, and care coordination in nursing practices. The primary studies were conducted in clinical care settings, such as long-term care settings, intensive care, or emergency departments in hospitals or primary care settings.

Seven SRs reported the usual or manual care group as the control groups; however, in the remaining SR [16], such information was not clearly reported. Li et al [23] specifically described the dosage of nursing interventions, which were assisted by AI-driven conversational agents, as reported in the primary studies.

Methodological Evaluation Results

Table 3 presents the quality assessment results of the 8 SRs. The JBI Critical Appraisal Checklist tool does not have cutoff scores; however, study scores ranging from 8 to 11 are referred to as high-quality studies, indicating a low risk of bias [27]. The review by O'Connor et al [24] scored 9 because they did not clearly and adequately report the resources that were used for the study searches and the methods used to minimize data extraction errors. The other 7 SRs scored between 10 and 11, clearly indicating the methodological directions in their reviews. Thus, all the SRs indicated a low risk of methodological bias.

Main Patient Outcomes

Overview

Among the 8 included SRs, the primary patient outcomes of AI-based nursing interventions were categorized into 3 common domains: (1) predictive outcomes (n=5), (2) psychosocial outcomes (n=5), and (3) hospital utilization outcomes (n=2; Tables S2 and S3 in Multimedia Appendix 1). Table 2 summarizes the common outcomes of these reviews. Due to the heterogeneity of the results, the findings are synthesized narratively.

Predictive Outcomes

In the 5 SRs that reported predictive outcomes, the predictions of adverse events, such as disease-related complication risks, mortality risks, and possible hospital utilization, were commonly reported using predictive algorithms [15-17,24,25].

Three SRs reported predicted possible complications related to diseases using AI-based nursing interventions [15,16,24]. In a high-quality review, Gosak et al [16] reported that nursing interventions applying AI techniques could predict the possible complications of type 2 diabetes mellitus. In this review, the risks of neuropathy, nephropathy, and retinopathy associated with diabetes were precisely predicted using AI prediction algorithms, such as penalized regression, random forest, and neural networks. Bressler et al [15] predicted the mortality risks of patients at 6 months, 1 year, and 2 years. These predictions enabled the early and timely detection of nurses' care interventions. O'Connor et al [24] reported the predicted risk of complications in patients with cancer in 17 primary studies. Yi et al [25] reviewed emergency triage predictions and found that intervention groups for which AI models were applied showed 0.9% more accurate predictions in emergency triage than those shown by control groups. In addition, the accuracy of emergency triage prediction rates ranged from 80.5% to 99.1% in the 4 primary studies. Thus, the results indicated that AI-based interventions had an impact on predicting adverse outcomes in patients.

Two SRs reported predictions of unplanned hospital utilization [17,24]. In the study by O'Connor et al [24], the length of hospital stay was predicted using 2 primary studies, with a conclusion of a significant improvement in the reduction of length of hospital stay predictions. Hu et al [17] predicted ICU readmissions using pooled results from a meta-analysis of 56 primary studies. They found that ICU readmissions within 30 days showed higher sensitivity (0.789, 95% CI 0.751-0.824) and specificity (0.835, 95% CI 0.805-0.860); sensitivity and specificity within 7 days were 0.462 (95% CI 0.118-0.846) and 0.788 (95% CI 0.448-0.945), respectively. Hu et al [17] reported that using short-term expectations to predict ICU readmissions is more complex.

Psychosocial Outcomes

Five SRs reported patients' psychosocial outcomes as results of AI-based nursing interventions [4,15,22-24]. In the SRs, patients' self-reported outcomes, such as quality of care, patient safety, patient satisfaction, and depressive symptoms, were measured.

Regarding the quality of care, 2 SRs demonstrated that the quality of care increased [15,24]. However, Raymond et al [4] reported mixed results in a high-quality SR. There was an improvement in the quality of care provided by NPs in 8 primary studies; however, no improvement was reported in 1 study. The results of patient safety outcomes were mixed. In the study by Kurniawan et al [22], AI-based nursing interventions could not support patient safety. Raymond et al [4] reported improvements in patient safety in 3 primary studies. Regarding patient satisfaction outcomes, Kurniawan et al [22] reported significant differences between groups in 7 primary studies after applying AI-based nursing interventions. Two SRs that reported depression as the primary outcome of AI-based nursing interventions for chronic illnesses [4,23] reported a significant reduction in depression in their 5 included primary RCTs. However, Kurniawan et al [22] reported no differences between the intervention and control groups in 3 studies. Therefore, the impact of AI-based nursing interventions on psychosocial outcomes remains inconclusive.

Hospital Utilization Outcomes

Two SRs reported total hospital utilization outcomes resulting from AI-based nursing interventions for chronic illnesses [4,15]. Both SRs investigated hospital readmissions and health care–related costs, and the results were conclusive. In the review by Bressler et al [15], 60- and 90-day hospital readmissions were significantly decreased in 1 primary study. Similarly, Raymond et al [4] reported that 2 primary studies showed significant reduction in rehospitalizations. Both SRs reported cost savings in intervention groups compared with control groups in hospital-based settings [15] and hospital care, especially in emergency care settings [4]. Both SRs, which were high-quality reviews, concluded the cost-saving capabilities of AI-based nursing interventions.

Discussion

Principal Findings

The integration of AI techniques into patient care has been used by nurses in various health care settings and has been reported to improve patient health care outcomes. This umbrella review expands on the current inconclusive results of AI-based nursing interventions to provide robust evidence on AI-based nursing interventions for chronic illnesses. The first aim of this umbrella review was to summarize nursing interventions that applied AI in caring for patients with chronic illnesses in health care settings, which may have affected patients' health care outcomes by analyzing individual SRs conducted in 7 countries. In this study, we synthesized the findings from 8 SRs focusing on AI-based nursing interventions for chronic illnesses that were conducted using 143 primary studies. All 8 SRs were published recently within the past 5 years, from 2021 to 2025. This study identified the types of AI techniques and algorithms used in recent evidence-based research. Regarding the AI techniques applied in nursing interventions, ML, decision-support systems, and DL, which is a subset of ML [28], were identified in the included SRs. These findings should be interpreted in the context of the specific AI modality rather than as evidence for a single homogeneous category of AI-based nursing interventions.

XSL•FO
RenderX

Among the AI algorithms, logistic regression models were most frequently used in the included reviews, as 5 of the SRs focused on predicting adverse outcomes.

Based on the secondary aim of this review, we synthesized 3 primary and common patient outcomes—predictive, psychosocial, and hospital utilization outcomes. This review identified the advantages of AI-based nursing interventions in predicting adverse events and hospital utilization outcomes. According to the SRs, applying AI algorithm models to intervention groups enabled better prediction of potential risks in patients with chronic illnesses, such as complications and unplanned hospital utilizations, compared with control groups without AI assistance. Chronic illnesses are associated with multiple comorbidities and complications [29]; thus, early-detection systems using AI are important [8,30]. Consistent with previous reviews, AI-based predictive models impact disease-related risk predictions [31,32]. In this umbrella review, we found that nurses could identify the possible risks of adverse events during AI-assisted nursing interventions. Subsequently, the nurses perceived patients' care needs with AI algorithms and proactively provided appropriate care for patients with chronic illnesses to prevent possible adverse events [16,25]. From the included SRs, we pooled data to predict unplanned ICU readmissions using the AI technique for critical care nurses [17]. The results showed that applying AI techniques affected nurses' practice, ensuring the prioritization of high-risk patient care. However, there could be accuracy issues and an algorithm risk of bias in AI-assisted predictions [17,25]. Thus, more rigorous AI models that can support nurses' interventions and larger datasets to critically predict chronic illness risks are required.

This umbrella review also revealed reductions in hospital readmissions and health care–related costs. Two SRs reported that AI-based nursing interventions significantly decreased hospitalization and health care costs for chronic illnesses [4,15]. The results regarding hospital utilization outcomes are supported by multidisciplinary studies on patients at high risk or receiving postoperative care [9,33]. In this review, we concluded that hospital utilization prediction was effective; however, 2 of the included SRs (4 primary studies) reported an impact on chronic illnesses. Furthermore, none of the SRs specifically compared the full economic analysis related to hospital use. More robust evidence that includes a large dataset and an elaborate analysis of the impact of AI-based nursing interventions on hospital utilization and cost analysis for chronic illness in health care settings is recommended.

The results regarding psychosocial outcomes were inconclusive. This umbrella review found mixed results on the safety, quality of care, satisfaction, or depression status among patients with chronic illness. Owing to the complex and wide range of psychological outcome measurements, SRs reported varied outcomes. One study demonstrated a false alarm regarding patients' adverse outcomes; thus, it reported no effectiveness of AI-based interventions on patient safety [22]. Recently, some nursing reviews have explored patient safety outcomes using AI [30,34]. However, the results have been inconclusive. Therefore, more studies on clear psychosocial measures of psychological outcomes after AI-based nursing interventions are required to provide evidence.

In the included SRs, evidence regarding the effectiveness of AI-based theoretical frameworks, specifically which AI type or algorithm effectively affects patient outcomes, is limited. In evidence-based practice, it is imperative to have theoretical frameworks that can be accepted as part of AI technology in nursing. One SR by Hu et al [17] concluded that ML outperformed other algorithms in predicting chronic illness outcomes. This finding is congruent with previous reviews, indicating that ML has been the most useful AI technology for nursing interventions [5]. Recent studies have demonstrated that AI models with AI algorithms are highly accurate in predicting patient outcomes for specific diseases in nursing research [5,10]. However, in this umbrella review, none of the SRs indicated that AI algorithms outperformed others in patient outcome predictions, nor did any show that AI algorithms were mostly used to predict patient outcomes. Further empirical studies are required to identify successful implementations of AI algorithm-optimized nursing interventions that are most useful for chronic illness care provision. Furthermore, theoretical frameworks for AI, targeting chronic illness management, should be established to implement AI-based nursing interventions.

When analyzing such AI-based nursing interventions regarding patient outcomes, it is necessary to clearly and robustly include complex datasets. Moreover, it is imperative to combine and refine all nurses' clinical notes, including texts from other health care professionals, to identify the most effective AI algorithms or types [24]. It is important to include nursing notes or unstructured texts when analyzing patient outcomes in AI-based nursing interventions for robust data analysis [4,15,17,24]. Several SRs have reported that nurses' free-text documentation and clinicians' notes are useful for AI-based model development and for predicting patient outcomes [4,15]. Hu et al [17] suggested that ML outperformed other methods in predicting patient outcomes; however, they used only structured datasets and ignored clinical notes. Thus, it may be insufficient to conclude that ML is a promising AI technique for nursing interventions in care provision for chronic illness. It is recommended to use both structured and unstructured data, such as nursing notes, to predict outcome measurements, along with AI-based techniques to eliminate the risk of data bias.

Strengths and Limitations

One strength of this umbrella review is that the 8 SR results included 41 RCTs and experimental design studies, which is a little less than half of the 143 primary studies. A recent review reported that there is a dearth of experimental studies on AI-based intervention in nursing, and it may be possible to prove the effectiveness of AI on patient outcomes in nursing research [5]. In addition, this review provides evidence that elucidates the impact of AI-based nursing interventions on related patient outcomes due to the high methodological quality of SRs.

This study has a few limitations. First, we identified and synthesized 3 common patient outcomes from 8 SRs. This review identified 3 dominant patient outcomes as the impact of AI-based nursing interventions. There could be more positive outcomes and benefits of AI-based technologies. Moreover,

XSL•FO
RenderX

substantial heterogeneity in AI intervention types, outcome measures, patient populations, chronic illness types, and study designs limited the feasibility of conducting a quantitative meta-analysis. Therefore, this review could only aggregate and summarize the findings narratively. More frequently, pooled results reporting patient outcomes with meta-analytical methods are desirable. Given the heterogeneity of AI technologies, intervention characteristics, and outcome measures, these findings should not be interpreted as evidence supporting the effectiveness of AI-based nursing interventions as a homogeneous entity. Second, the 8 included SRs focused only on the effectiveness of AI technologies in participants with chronic illnesses. There was limited information about the dosage of the interventions, indicating a dearth of information about the frequency or duration of AI-based interventions. Only the review by Li et al [23] reported the dosage of interventions in their primary RCTs. Thus, this umbrella review had limited information from the included SRs to perform a dosage analysis of AI techniques and nursing interventions and its impact on patient outcomes. Third, this umbrella review included SRs published in peer-reviewed journals from 5 electronic databases in the past 5 years and excluded gray literature to meet the aim of this review. Thus, some data may have been missing. Furthermore, this study may have a potential overlap of primary studies across the included SRs, which may introduce double-counting bias and affect the validity of the findings. Fourth, participants with chronic illnesses included in the SRs were recruited within health care settings, such as emergency departments or long-term care. There was limited information about their age, number of chronic diseases, or any complications. Fifth, potential publication bias could have been present in the 8 SRs, as they had the tendency to report positive results. Finally, this review included only SRs published in English.

Several challenges should also be considered when integrating AI-based technologies into nursing practice. Algorithmic bias, data quality limitations, and the limited explainability of some AI models may affect the reliability and transparency of AI-assisted clinical decision-making. In addition, interoperability with existing electronic health record systems remains a significant barrier in many health care settings. Clinician trust, ethical considerations, data privacy, and regulatory compliance must also be addressed to support the safe and effective implementation of AI-enabled nursing interventions. Future research should evaluate not only effectiveness but also implementation feasibility, acceptability, and sustainability in clinical practice.

Implications for Nursing Practice and Policy

For frontline nurses caring for patients with chronic illnesses, the findings of this umbrella review will enable them to identify patient risks and effectively integrate AI-based techniques into clinical nursing practice. Nurses and NPs can use the results of this umbrella review as evidence for practice in chronic illness care provision. The ICN emphasizes that nurses should participate in and be educated on the development of AI-based interventions in health care systems and implement these AI technologies in their clinical practice to achieve better patient outcomes and patient safety [2]. Evidence exists on risk predictions, hospital utilization, and health care costs in AI-based nursing interventions for chronic illnesses. Thus, nurses need to explore more patient outcomes, including the investigation of inconclusive psychological outcomes of chronic illnesses. Furthermore, it is recommended that nurses should implement and lead the application of AI in clinical practice to improve patient-centered care [2].

Nursing leaders in global nursing organizations prioritize AI in nursing research, education, and practice [1,2]. The ICN has announced the importance of digital technology education in nursing and nurses' competency in using AI systems [2]. They must continuously leverage the empowerment of the nursing workforce within an AI health care system. They require stable support in nursing research, practice, and policy development domains to continuously realize the value of AI in clinical practice.

Conclusion

This umbrella review is the first to synthesize recent SRs examining the impact of AI-based nursing interventions on chronic illnesses in health care settings. The findings suggest that AI-based nursing interventions may have potential benefits for predictive outcomes and for reducing unplanned hospital utilization. However, evidence regarding psychosocial outcomes remains conflicting and inconclusive. These results should be interpreted cautiously due to the limited number of included reviews and the heterogeneity across studies. Therefore, further high-quality studies are needed to strengthen the identified evidence and optimize nurse-led AI-based interventions across different outcome domains in clinical practice.

Abstract

Background: Digital health refers to the field of knowledge and practice associated with the development and use of digital technologies to improve clinical practice and health outcomes. Knowledge of digital health technology is becoming essential for all nurses and health providers.

Objective: This study aims to present the results of the systematic reviews that were used to inform the recommendations in a best practice guideline (BPG) following the GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) approach. Reviews focused on digital health education for nurses and health providers, peer champion models, and the use of predictive analytics in digital health environments.

Methods: The BPG team, in collaboration with a panel of 17 experts, conducted 5 systematic reviews to address 5 recommendation questions. Systematic searches looked for relevant studies published in English from January 2017 to July 2022 from 10 databases. The GRADE approach was used to synthesize and evaluate the quality of evidence, ensuring the guideline aligned with international reporting standards.

Results: A total of 18 articles across 4 systematic reviews met the inclusion criteria. From these reviews, 4 corresponding recommendations were drafted for nurses and health providers. The strength of the recommendations was determined through discussion and consensus by the expert panel using the GRADE approach. Among all, 1 systematic review resulted in no recommendation due to insufficient evidence.

Conclusions: The BPG on digital health provides 4 evidence-based recommendations for nurses and health providers on how to incorporate digital health technologies into clinical practice. This BPG is intended to be used across all health care settings.

KEYWORDS

digital health; nursing; electronic health; health informatics; clinical guidelines

Introduction

Over the last decade, there has been an increased uptake of digital health technologies across global health care systems [1]. Digital health is a broad term that refers to the field of knowledge and practice associated with the development and use of digital technologies to improve health [2]. Digital health technologies refer to tools, systems, or devices that can generate, create, store, or process data, enabled through microprocesses that are programmed to perform specific functions [3]. Specifically in health care settings (or digital health environments), digital health technologies may encompass eHealth, mHealth, health informatics, artificial intelligence (AI), machine learning, big data, robotics, and advanced computing

XSL•FO
RenderX

sciences [2]. A digital health environment refers to any setting where health providers, informatics professionals, administrators, managers, and persons or families receiving care work in supportive teams to leverage digital tools, technologies, and services to optimize care delivery and empower and activate people to manage their health and wellness [4]. Nurses and health providers use a variety of digital health technologies in practice, including electronic health records, clinical decision support systems (CDSSs) that use predictive analytics, robotics, mobile apps, virtual care platforms, wearable devices, remote monitoring systems, smart home technologies, and others [4]. As nursing practice continues to evolve across all settings and sectors to incorporate these technologies, ongoing education is essential for nurses and health providers to deliver comprehensive clinical care [4,5].

Digital health technologies are advancing at a rapid pace; however, challenges remain in supporting nurses and health providers in using these technologies safely and effectively [6]. Educators and health systems leaders must work to evolve the understanding of novel nurse-patient interactions involving digital health technologies, alongside other core nursing topics [5]. Through further education and training, nurses will have a greater understanding of how both new and existing digital health technologies may impact clinical processes and communication patterns between patients, caregivers, and the interprofessional team [7]. Furthermore, nurses in clinical practice will require initial and ongoing professional development opportunities to aid in the use of digital health technologies [8,9]. Effective training will enable nurses to use these technologies both safely and effectively. Many of the good practice statements, recommendations, and resources within this best practice guideline (BPG) provide guidance on education for nurses and health providers to address this growing need.

The Registered Nurses' Association of Ontario (RNAO) published a new BPG entitled *Clinical Practice in a Digital Health Environment* in March 2024 [4]. The BPG was developed with an expert panel, which included 17 digital health experts representing diverse backgrounds including nursing, education, research, allied health, and people with lived experience. The purpose of the BPG is to provide evidence-based recommendations that foster nurses' ability to maintain, advance, and strengthen professional practice in the context of a digital health environment [4]. The guideline is intended for all nurses (registered nurses, nurse practitioners, and registered practical nurses), nursing students, as well as members of the interprofessional health care team, educators, administrators, executives, policymakers, researchers, and people with lived experience. Within the context of this BPG, people with lived experience refer to patients and family within health systems wherein digital health is used.

The aim of this paper is to describe the BPG development process and the results from 4 systematic reviews that were used to inform the recommendations in the BPG, following the GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) approach [10]. Additionally, this paper will reflect on the health equity considerations, research gaps, and limitations noted during guideline development, related to the integration of digital health technologies in clinical practice.

Methods

Development Approach

RNAO's BPG development team used the GRADE approach to develop this guideline, which is in line with international reporting standards [10]. GRADE is a transparent and structured process to evaluate the certainty of a body of evidence from systematic reviews in order to develop sound, evidence-based recommendations in guidelines [10]. The systematic reviews were conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [11] (Checklist 1). The following section will describe how the purpose and scope of the guideline were determined, the 5 systematic reviews that were conducted, and the resulting 4 recommendations that were drafted following completion of the systematic reviews.

Scoping the Best Practice Guideline

To determine the purpose and scope of this BPG, the guideline development team conducted an environmental scan on existing clinical guidelines on this topic and appraised those guidelines. Two guideline development methodologists (GDMs) determined inclusion or exclusion criteria and searched an established list of websites for guidelines and other relevant content (eg, quality standards) published between January 2016 and March 2021 (Multimedia Appendix 1). Expert panel members were also asked to suggest additional guidelines for review. Guidelines were reviewed for content, applicability to health provider scope of practice, accessibility, and quality. Each GDM individually evaluated guideline quality using the Appraisal of Guidelines for Research and Evaluation II instrument [12]. Through this process, it was determined that no guidelines had been developed addressing evidence-based recommendations in this unique and growing area, especially as it relates to nurses and clinical practice.

The team also completed a preliminary literature review to examine available evidence on digital health for nurses, including how digital health technologies are being integrated into the nursing process; how digital health technologies are facilitators and/or barriers for nurses when maintaining and advancing professional practice; and what outcomes are used to measure the impact of using digital health technologies in nursing practice. Two databases were searched for literature (CINAHL and MEDLINE) between January 2016 and May 2021. Screening for eligibility was conducted independently by 2 GDMs with conflicts resolved through consensus. Data extraction was completed for the included studies on a customized Microsoft Excel sheet developed by the GDMs. Elements of data extraction (such as study setting, intervention, and outcomes) were determined by the GDMs. An analysis of themes across the studies was synthesized, and the themes, interventions, and outcomes were later presented to the expert panel.

GDMs also conducted 22 key informant interviews and 2 discussion groups with diverse experts in the field. Key

XSL•FO
RenderX

informants included people with lived experience, direct care health and social service providers, and researchers selected based on their knowledge and expertise related to the BPG topic. Snowball sampling was also used to recruit key informants. See Textbox 1 for a description of the questions asked during the interviews. For the discussion groups, 3 sessions were convened with a total of 18 nursing students, clinical informatics nurses, and frontline nurses to understand the needs of nurses within digital health environments. GDMs used inductive qualitative content analysis to analyze data collected from key informant interviews and discussion groups, and this information was also presented to the expert panel.

Textbox 1. Key informant interview questions.

- How can digital health technologies impact the quality of care a person receives?
- How can digital health technologies promote or hinder the therapeutic nurse-client relationship?
- In what ways can a digital health environment enhance or hinder patient care delivery for underserved populations?
- What skills or competencies do nurses require in order to maintain professional practice in a digital health environment?
- What skills and competencies do nurse leaders require in order to support the interface between nursing clinical practice and digital health technology?
- What challenges do nurses face when working in a digital health environment?
- What challenges or struggles do you face in your current practice related to the use or implementation of digital health technologies?
- What challenges do nurses face when trying to engage in the design, development, and evaluation of digital health environments?
- What policies or practices can help nurses maintain professional practice in a digital health environment?
- What outcomes should we explore in the literature to measure the impact of using digital health technologies in clinical nursing practice?
- What should the scope of this guideline be?
- What should this best practice guideline (BPG) address in order to be most useful in practice for nurses and people receiving care?
- Are there any last thoughts on what is important for us to consider when starting the development of this BPG?

Identifying Priority Recommendation Questions and Outcomes

The BPG development team assembled a panel of 17 experts, including 2 cochairs, from nursing practice, research, education, and policy, as well as other members of the interprofessional team, and people with lived experience representing a range of sectors and practice areas. The BPG was supported by 2 cochairs with relevant clinical and research experience, one of whom was a doctorate-prepared registered nurse, and the other cochair led the pan-Canadian Electronic Health Record Clinical Engagement Strategy for 6 years at Canada Health Infoway. The expert panel also included representatives from different geographical areas, including rural, suburban, and urban. From July to December 2021, 4 panel meetings were held to determine the BPG's purpose, scope, and research questions that informed the systematic reviews. During the first orientation meeting, the expert panel was introduced to RNAO's BPG program, the systematic review process, and the GRADE approach. Additional electronic materials were also sent to the panel to familiarize them with the BPG development process and the GRADE approach. Declarations of conflicts of interest that might be construed as constituting a perceived and/or actual conflict were made by all members of the expert panel prior to their participation in guideline development work, and on an ongoing basis.

During the initial phase of the guideline development process, the expert panel prioritized 4 research questions and corresponding outcomes deemed most important to this topic. An amendment to the PROSPERO registration was made following these initial meetings, once the panel determined through email correspondence that a fifth research question should be added. Textbox 2 displays the final recommendation questions and outcomes that informed focused research questions for the systematic reviews.

XSL•FO
RenderX

Textbox 2. Recommendation questions and outcomes in the clinical practice in a digital health environment best practice guideline.

Recommendation question 1: Should practical (eg, hands-on) professional development education focused on the use of digital health technologies within an organization be recommended or not for all nurses?

Outcomes: nurse competence (with using technology), nurse acceptance of technology, nurse-sensitive outcomes (eg, falls, pressure injuries, and pain), nurse involvement in the technology life cycle, nurse confidence (with using technology), and nurse-person therapeutic relationship.

Recommendation question 2: Should education about relational care and interpersonal communication skills be recommended or not for nurses practicing in virtual care settings and in-person digital health environments?

Outcomes: person or caregiver or family experience or satisfaction, nurse competence (with using technology), nurse confidence (with using technology), nurse-person therapeutic relationship, and person or caregiver or family involvement and engagement in care.

Recommendation question 3: Should the implementation of interdisciplinary peer champion models in health service organizations be recommended or not to facilitate education for health providers on the use of digital health technologies?

Outcomes: health provider competence (with using technology), health provider adoption of technology, health provider confidence (with using technology), health provider sensitive outcomes (eg, pressure injuries and pain), and sustainability of education (ie, knowledge and skills retention).

Recommendation question 4: Should the use of predictive analytics software or systems (eg, command centers and risk assessment software tools) for nurses providing care in all practice settings be recommended or not to inform clinical decision-making and improve clinical outcomes?

Outcomes: proactive or anticipatory care, critical incidents, failure to rescue, consistent application of evidence-based practice, and nurse-sensitive outcomes (eg, falls, pressure injuries, and pain).

Recommendation question 5: Should a distributive model (vs no distributive model or any other type of change management model) be recommended to integrate digital health competencies into the professional practice roles and responsibilities of nurses at all levels within an organization?

Outcomes: nurse competence (with using technology), nurse engagement (with using, developing, acquiring, and participating in education about the technology), nurse confidence (with using technology), person or caregiver or family experience or satisfaction, and nurses being able to define what their role is.

Systematic Retrieval of the Evidence

The systematic reviews for the guideline were registered with PROSPERO in 2022 (CRD42022321580). Upon consultation with the expert panel, 4 amendments were made to the original PROSPERO registered protocol. These included: (1) adding an additional database to search (IEEE Xplore) in April 2022, (2) adding an additional systematic review question (December 2022), (3) conducting indirect evidence searches (January 2023), and (4) publishing the final version of the guideline online (May 2024). All other systematic review methods followed the protocol outlined in the original PROSPERO registration.

Five separate systematic review search strategies were developed and run by an external health sciences librarian from the University Health Network after consulting with 2 GDMs (CB and LH). The systematic searches included peer-reviewed studies of any study design (eg, quantitative, qualitative, mixed methods, and systematic reviews) published in English from January 2017 to July 2022. The following databases were searched: MEDLINE, MEDLINE Epub Ahead of Print and In-Process, Embase, Emcare Nursing, Cochrane Central Register of Controlled Trials, Cochrane Database of Systematic Reviews, APA PsychInfo, CINAHL, and IEEE Xplore. Expert panel members were also asked to review their personal libraries for key studies not found through the above search strategies. For more details and the full search strategy used for each systematic review, please refer to Multimedia Appendix 2.

After conducting the initial searches, it was decided to look for further indirect evidence to support each question. Direct evidence comes from research that directly compares the interventions of interest when applied to the populations of interest and measures outcomes important to patients [13]. Evidence can be indirect if the population differs, the intervention differs, or outcomes differ from those of original interest [13]. The health science librarian conducted additional indirect evidence searches from January 2023 to March 2023 for systematic reviews published in English. The BPG team recognizes that direct evidence allows for more confidence in the results; however, in the absence of direct evidence, GRADE notes that indirect evidence can be used and downgraded accordingly [10,13]. The broader populations and interventions searched were considered sufficiently direct by the expert panel and in line with the original methodology. To ensure the most up-to-date evidence was included in the BPG, an update search was also conducted in English between January 2023 to January 2024 for recommendation questions 1 to 4. However, an update search for question 5 was not completed since a recommendation was not drafted for this area. For the full search strategies, see Multimedia Appendix 2.

Eligibility Criteria

All search results from the librarian were uploaded into DistillerSR software (DistillerSR Inc). All steps of the systematic review process were completed by 2 GDMs (CB and LH for the initial search and CB and LB for the update search). Two GDMs independently completed title and abstract screening using standardized screening guides developed by the GDMs. Screening guides were reviewed by senior members of the RNAO team prior to use. Studies included at this stage had the full text reviewed independently by both GDMs. Final inclusion was deemed appropriate if studies answered the research question, included prioritized outcomes, were published in English, and were accessible for retrieval. See Textbox 3 for inclusion and exclusion criteria, and Multimedia Appendix 2 for further details. Disagreements were settled by consensus. For the initial systematic search, any study design was eligible to be included. For the updated indirect systematic searches,

XSL•FO
RenderX

study designs were limited to systematic reviews and meta-analyses.

Textbox 3. Inclusion and exclusion criteria.

Inclusion criteria:

- A primary focus on the interventions of interest and the prioritized outcomes per research question
- A focus on digital health technologies
- Applicable to nurses or health providers providing care in all practice settings (including registered nurses, registered practical nurses, nursing students, and nurse practitioners)
- Applicable to all health or social service organizations, or academic institutions
- Published after January 2017
- Published in English
- Accessible for retrieval
- Conducted in any geographic region
- Peer-reviewed literature
- Any study design (eg, quantitative, qualitative, mixed methods, and systematic reviews), but when conducting the indirect searches, only systematic reviews and meta-analyses were included.

Exclusion criteria:

- Topic NOT related to the interventions or prioritized outcomes per research question
- Dissertations, commentaries, narratives, discussion papers, case studies, expert reports, consensus documents, and studies with no specific methodology
- Studies not published in English
- Unpublished literature (eg, gray literature)
- Studies published prior to 2017

Data Extraction and Quality Appraisal

Data extraction was completed on the included studies for each research question. The included studies were divided between GDMs and each reviewer independently extracted details from their assigned studies using standardized Excel sheets that were developed by the RNAO team (Multimedia Appendix 3). Each Excel sheet had a designated outcome for which study details were recorded. Details such as the setting, intervention and control description, the outcome and how it was measured, and study results were recorded by 1 GDM. Any harms (such as adverse effects), information on values, preferences, and health equity were also recorded. The second GDM independently reviewed the extracted data for accuracy. Quality appraisal of each article was completed independently by each GDM. The Cochrane Risk of Bias 2.0 tool [14] was used to appraise randomized controlled trials (RCTs), the risk of bias in nonrandomized studies—of interventions (ROBINS-I) tool [15] was used to appraise nonrandomized studies, and the risk of bias in systematic reviews (ROBIS) tool [16] was used to appraise systematic reviews. If a systematic review received a low risk of bias score using the ROBIS tool, and the review's authors completed a risk of bias assessment within the paper, those assessments were also considered when conducting the GRADE consensus. After quality appraisal was completed by both GDMs, GRADE consensus was completed to assess the certainty of evidence for each outcome for each research question. GRADE uses five categories to rate the certainty of evidence as high, moderate, low, and very low by examining (1) risk of bias, (2) inconsistency, (3) imprecision, (4) indirectness, and (5) publication bias [10]. After the 5 categories had been graded, a certainty of evidence was determined for each of the 4 drafted recommendations corresponding to the research questions.

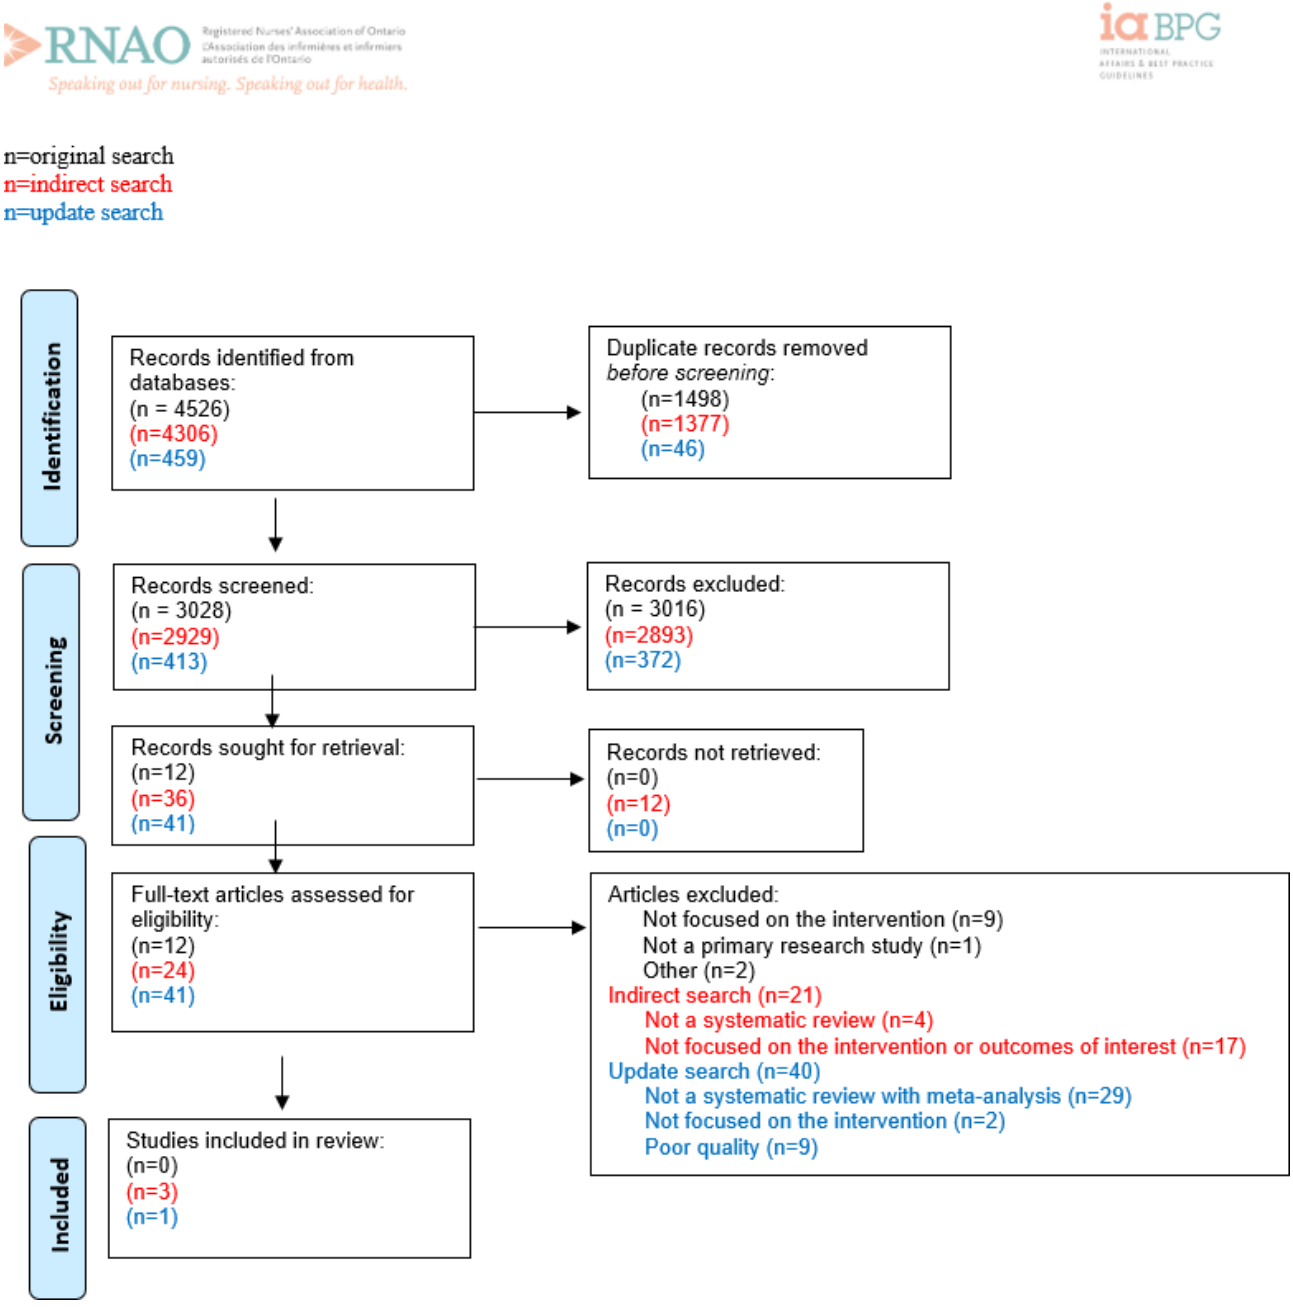
Drafting Recommendations in the BPG

As per the GRADE methodology, the GDMs created an evidence profile (EP) and evidence to decision (EtD) framework for each recommendation [4,10]. The EP outlined details regarding the certainty of evidence across outcomes and the GRADE domains (Multimedia Appendices 4-7). The EtD frameworks provided a narrative summary of the evidence for draft recommendations, described the certainty of evidence, and provided details around values and preferences regarding the intervention, as well as health equity considerations found in the systematic reviews. Expert panel members were provided with the EPs and EtD frameworks to review prior to 3 (virtual) half-day meetings to determine the direction (ie, a recommendation for or against an intervention) and the strength (ie, strong or conditional) of the BPG's recommendations. A conditional recommendation is one for which the desirable effects probably outweigh the undesirable effects, and there is a need to consider more carefully than usual the individual's circumstances, values, and preferences [10]. If there was insufficient direct or indirect evidence to develop a recommendation, the expert panel also had the option not to proceed with a recommendation. The expert panel determined that current evidence was insufficient to assess the certainty of

XSL•FO
RenderX

effects of a distributive model (recommendation question 5) compared to other types of change management models to integrate digital health competencies into the professional practice roles and responsibilities of nurses within an organization; thus, no recommendation was made.

The recommendations and draft BPG also underwent several rounds of internal and external review prior to publication [17]. External reviewers for RNAO BPGs are identified through a public call issued on the RNAO website [17]. For this BPG, the written external review process was completed between September 14, 2023, and October 23, 2023. External reviewers with diverse perspectives, such as nurses and health providers, administrators, researchers, educators, nursing students, and people with lived experience, provided direct feedback.



Results

Summary of Results

For PRISMA flow diagrams, see Figures 1-5. Two reviewers screened over 22,500 articles for the 5 original research questions. After screening, the 2 GDMs reviewed 253 full-text articles for relevance to the research questions and outcomes, and 18 articles met the requirements to inform the recommendations. It was determined through consultation with the expert panel that question 5 did not have enough evidence to support the recommendation, so a recommendation was not developed. Thus, 4 recommendations were drafted (one per each of the corresponding systematic reviews), and the strength of the recommendations was determined through discussion and consensus by the expert panel, based on the available evidence (Table 1).

Table . Summary of recommendations in the best practice guideline.

Recommendation	Strength of recommendation
Recommendation 1.0: the expert panel suggests that health service and academic organizations provide ongoing education to nurses and health providers that includes hands-on training for the use of digital health technologies.	Conditional
Recommendation 2.0: the expert panel suggests that health service and academic organizations provide ongoing education to nurses and health providers that focuses on interpersonal communication skills when using digital health technologies.	Conditional
Recommendation 3.0: the expert panel suggests that health service organizations implement interdisciplinary peer champion models to facilitate education for nurses and health providers on the use of digital health technologies.	Conditional
Recommendation 4.0: the expert panel suggests that health service organizations implement CDSS[a] or early warning systems that use artificial intelligence–driven predictive analytics to support nurses' and health providers' clinical decision-making.	Conditional

[a]CDSS: clinical decision support system.

Recommendation 1.0: The Expert Panel Suggests That Health-Service and Academic Organizations Provide Ongoing Education to Nurses and Health Providers That Includes Hands-on Training for the Use of Digital Health Technologies

Practical or hands-on education refers to deliberate practice, hands-on training, or simulation training (ie, more than just viewing e-learning modules) [4]. The intervention of interest examined whether practical or hands-on education for professional development was more effective than standard education (ie, no-hands-on education component) when training nurses and health providers on the use of digital health technologies [4]. Four meta-analyses informed this recommendation [18-21]. The 4 meta-analyses were assessed for risk of bias using the ROBIS tool, and each one had a low risk of bias [18-21]. Studies included in the meta-analyses were assessed by the authors of the meta-analyses, and they used the Cochrane risk-of-bias 2.0 tool for RCTs, the ROBINS-I tool for nonrandomized studies, and the National Institute for Health and Care Excellence quality appraisal checklist [18-21]. Nine studies within the meta-analyses had a critical risk of bias, 18 studies had high risk of bias, 4 studies had unclear risk of bias, and 1 study had low risk of bias [18-21]. There were concerns noted around allocation concealment, blinding, incomplete outcome data, missing outcome data, selection of the reported results, confounding, allocation concealment, and selection of participants [18-21].

Examples of practical or hands-on professional development education discussed in the studies included nurses practicing using electronic health records while being supervised in a computer lab, and hands-on training for using virtual care platforms [18-21]. For more details on the study designs, the risk of bias assessments, how the interventions were delivered, and outcome measures, refer to the GRADE EP found in Multimedia Appendix 4.

The results of the systematic review suggest that hands-on education for nurses and health providers may improve nurses' competence and confidence, and the nurse-person therapeutic relationship (while the technology is used with the person receiving care). The expert panel determined that the overall evidence was of very low certainty due to the risk of bias in the primary studies, indirectness in the outcomes, inconsistency in the results, and imprecision due to small sample sizes [4]. Based on this certainty of evidence, the panel determined the strength of the recommendation to be conditional.

Recommendation 2.0: The Expert Panel Suggests That Health-Service and Academic Organizations Provide Ongoing Education to Nurses and Health Providers That Focuses on Interpersonal Communication Skills When Using Digital Health Technologies

Interpersonal communication describes the communication between a nurse or health provider and a person receiving care. It includes both verbal and nonverbal communication, as well as leading and listening skills that enable a person to interact positively with others in an effective manner [4,22]. The types of education varied across the studies and included didactic and simulation-based education (eg, simulated patients) to improve medical students' interpersonal communication during consultations; training on incorporating computers or electronic health records into nurse-patient encounters; and education on telehealth communication strategies (eg, phone and video consults) [23-29]. Most studies examined focused on medical students [23-27,29], and 1 study focused on nursing students [28].

Seven studies informed this recommendation, including 1 systematic review, 5 additional nonrandomized studies, and 1 mixed methods study [23-29]. The review was assessed using the ROBIS tool and had a low risk of bias [23]. Studies included in the review were assessed by the review authors in accordance with the Cochrane Handbook for Systematic Reviews of Interventions; none were deemed as having a high risk of bias overall [23]. Nonrandomized studies and the mixed-methods

XSL•FO
RenderX

study were assessed using the ROBINS-I tool, and there was a critical risk of bias related to confounding variables, deviations from the intended interventions, missing data, measurement of outcomes, and selection of the reported results [24-29].

The 7 studies illustrated that there may be benefits when health service and academic organizations provide nurses and other health providers with education about the importance of interpersonal communication when using digital health technologies [4,23-29]. Benefits may include improved person, caregiver, or family experience or satisfaction with care, and increased competence and confidence among nurses; however, the overall certainty of the evidence using the GRADE methodology was very low, due to risk of bias in the seven studies, few participants, and inconsistency in results [4]. Based on these factors, the expert panel determined the strength of the recommendation to be conditional. For more details on the study designs, risk of bias assessments, how the interventions were delivered, and outcome measures, refer to the GRADE EP in Multimedia Appendix 5.

Recommendation 3.0: The Expert Panel Suggests That Health Service Organizations Implement Interdisciplinary Peer Champion Models to Facilitate Education for Nurses and Health Providers on the Use of Digital Health Technologies

Interdisciplinary peer champions refer to super-users or champions that are nurses or other members of the interdisciplinary health care team with expertise and additional training in digital health [4]. These individuals function as a resource for other staff, helping to answer questions and teach staff about new technology during implementation. Peer champions can also help identify gaps in the technology or its implementation in practice. This recommendation examined the effects of organizations implementing peer champion models to facilitate education for staff about digital health technologies.

One systematic review of 6 RCTs and 2 nonrandomized single-arm studies informed this recommendation [30-32]. The review was assessed using the ROBIS tool and had a low risk of bias [30]. Studies included in the review were assessed by the review authors using the Cochrane risk-of-bias tool for RCTs; 5 studies had a high risk of bias and 1 study had an unclear risk of bias [30]. The nonrandomized studies were assessed using the ROBINS-I tool, and there was a critical risk of bias related to confounding variables, missing data, measurement of the outcomes, and selection of the reported results [31,32].

The use of peer champions in health service organizations may increase health providers' adoption of technology and health provider competence [4]. The overall certainty of evidence was low due to a serious risk of bias in the individual studies and a low number of participants [4]. Based on the available evidence, the expert panel determined the recommendation to be conditional. For more details on the study designs, risk of bias assessments, how the interventions were delivered, and outcome measures, refer to the GRADE EP in Multimedia Appendix 6.

Recommendation 4.0: The Expert Panel Suggests That Health Service Organizations Implement Clinical Decision Support Systems or Early Warning Systems That Use AI-Driven Predictive Analytics to Support Nurses' and Health Providers' Clinical Decision-Making

CDSS or early warning systems refer to software found in risk assessment software tools, early warning systems, command centers, and other software systems that use AI machine learning algorithms to interpret data independently [4]. The recommendation question examined whether adding these systems benefits clinical decision-making for nurses and other health providers.

One systematic review of RCTs, 1 nonrandomized single-arm study, and 2 systematic reviews of nonrandomized studies informed this recommendation [33-36]. Included reviews were assessed using the ROBIS tool and had a low risk of bias [33,35,36]. Studies included in 1 review were assessed by the review authors using the Critical Appraisal Skills Programme checklist for RCTs; 2 studies had a low risk of bias and 1 study had a high risk of bias [33]. Concerns were noted around the lack of details describing the methods, and the lack of blinding [33]. Studies included in another review were assessed by the review authors using the Prediction model Risk Of Bias Assessment Tool; all 10 studies had high or unclear risk of bias [36]. The nonrandomized study was assessed using the ROBINS-I tool and had a critical risk of bias due to lack of control for confounding variables, deviations from the intended intervention, and selection of the reported results [34]. Studies in the final review were assessed by the review authors using the ROBINS-I tool; all 5 included studies had a critical risk of bias [35]. Concerns were noted around confounding, selection of participants, missing data, measurement of outcomes, and selection in reported results [35].

There may be benefits when implementing CDSS or early warning systems that use AI-driven predictive analytics to inform nurses' clinical decision-making, such as improved proactive or anticipatory care, decreased failure to rescue, consistent application of evidence-based practice, and improved nurse-sensitive outcomes [4]. The overall certainty of evidence was low due to risk of bias and few participants [4]. As evidence is still emerging on this topic and the results were mixed, the expert panel determined the strength of the recommendation to be conditional. For more detail on the study designs, risk of bias assessments, how the interventions were delivered, and outcome measures, refer to the GRADE EP in Multimedia Appendix 7.

Discussion

Digital Health Considerations

In 2019, the World Health Organization released a global strategy on digital health acknowledging the vital role digital health plays in planning and providing health services [2]. As digital health technologies become increasingly integrated into health care, nurses need leadership and guidance to safely and effectively use technology in practice. RNAO's BPG provides evidence-based recommendations to foster nurses' ability to maintain, advance, and strengthen professional practice in the context of a digital health environment [4]. The guideline's

XSL•FO
RenderX

recommendations focus on (1) hands-on education related to the use of digital health technologies, (2) education about interpersonal communication skills when using digital health technologies, (3) using interdisciplinary peer-champion models to provide education about digital health technologies, and (4) implementing CDSS that uses AI to support but not replace clinical decision-making. While not discussed in this article, additional good practice statements are also provided in the guideline [4].

While digital health has the potential to enhance the quality of care and address key health system challenges, the importance of considering the digital determinants of health, including digital literacy and the digital divide, to ensure equitable delivery of care must be considered. Digital literacy refers to a person's ability to effectively interact with digital technology, using skills required to find, understand, appraise, and apply health information specifically from electronic sources [37]. The digital divide refers to the gap between those who have access to digital technologies, including the internet, accessible health websites and portals, versus those who do not [38]. The World Health Organization's global strategy on digital health notes that digital technologies are to be adaptable to different countries and contexts to help address key health system challenges, while incorporating equity, diversity, and inclusion principles [2]. Unfortunately, the use of certain digital health technologies such as CDSS that use AI may be difficult to implement in less affluent health care systems due to the digital divide [39]. The effectiveness of implementing CDSS that use AI to detect changes in a patient's condition is also dependent on having staff who respond appropriately to these digital tools as well as nursing leadership to continuously oversee the refinement of CDSS and algorithms as needed. As outlined by Richardson et al [40] in their framework for digital health equity, there are several domains of equity including biological, behavioral, physical/built environment, sociocultural environment, and the health care system. The framework can help support the work of digital health technology developers to think about and incorporate principles of digital health equity from the very beginning of the technology development process [4,40]. The framework is also important for end-users, researchers, and health systems leaders, as digital health transformation requires health leaders at all levels to understand how the digital determinants impact health equity [4,40].

In addition to considering the digital determinants of health, when discussing the use of digital health technology with a person receiving care and/or their family, nurses must consider: their preferences and goals; capability and motivation for using technology; how the technology fits into their current care routines; and any costs associated with using the technology [4,41]. Digital health technologies have the potential to enhance a person's experience of the care they receive [5]; however, nurses must consider a person's values and preferences for using technology and ensure that using the technology does not negatively impact or compromise the nurse-patient therapeutic relationship [2,5].

Implementation and Evaluation Considerations

Evidence-based guidelines are effective when there are tools and strategies in place to facilitate their implementation into practice [12]. RNAO uses an integrated approach to ensure that guidelines are both trustworthy and applicable in real-world settings [17]. This BPG includes several tools to support its implementation, including implementation tips, supporting resources, appendices related to the recommendations, and good practice statements. The BPG also directs readers to RNAO's Leading Change Toolkit, which can be used to guide change initiatives, including the implementation of BPGs [42]. RNAO has a network of best practice champions who are the change agents that aid in the implementation of the guidelines, and Best Practice Spotlight Organizations® (BPSO®) internationally from over 13 different countries that partner with RNAO to systematically implement and evaluate RNAO's BPGs [17].

Finally, a monitoring and evaluation table outlines structure, process, and outcome indicators that health service organizations can use to monitor the impact of BPG implementation. Ongoing evaluation is crucial to support the uptake and impact of BPGs on person, organizational, and health systems outcomes [17]. RNAO houses 2 data systems to support BPSOs to monitor and evaluate BPGs: MyBPSO and Nursing Quality Indicators for Reporting and Evaluation® [17]. These 2 data systems are used by BPSOs to report evaluation and monitoring data. As of November 2025, implementation of this BPG has begun in BPSOs, and 1 large Canadian community hospital BPSO has demonstrated 99% (555/562) of nursing staff were compliant with orientation to technologies. Evaluation has also indicated that 84% (474/562) of nurses at this hospital reported comfort with hospital-based technologies to deliver care, and 30% (20,188/72,342) of patients enrolled in a digital patient portal over an 18-month period. Evaluation and monitoring of outcomes is ongoing, and it is anticipated that in the coming years, more BPSOs will implement this valuable BPG.

Future Research Considerations

The expert panel noted that although rigorous RCTs are needed, more exploration including qualitative research is also needed in the area of digital health as it pertains to nursing and clinical practice. For example, studies that examine the efficacy, accuracy, and generalizability of AI-driven predictive analytics, and qualitative studies exploring how nurses and health providers adapt their communication skills in digital health environments. National and international research institutes focused specifically on advancing digital health technologies and integrating digital health practices into clinical care for nurses and health providers would also be beneficial.

Limitations

A few limitations were noted by the expert panel and GDMs during the development of the BPG. First, research in digital health that is specific to nurses and clinical practice is an emerging area. As research is yet to be well established, most evidence for the prioritized research questions was of low or very low certainty; thus, all the recommendations contained in the BPG were deemed conditional. There were few well-designed RCTs, and many of the nonrandomized studies

XSL•FO
RenderX

had a high risk of bias, small sample sizes, and inconsistent results. In addition, due to the paucity of research evidence focused on nurses and digital health, the expert panel considered indirect evidence. According to the GRADE methodology, directness is assessed based on the relevance to the target population, intervention, and outcomes of interest [10]. Although GRADE methods allow for the use of indirect evidence, the reliance on indirect evidence due to insufficient direct evidence is a limitation in this BPG, recognizing that indirect evidence may introduce potential biases or uncertainties. The absence of research and use of indirect evidence is noted in the BPG as research gaps, stressing areas for further exploration.

Despite these limitations, expert panel members and additional external reviewers noted the need for guidance on this topic and the importance of publishing this guideline. Conditional recommendations are not to be seen as less important or less trustworthy; they simply imply that there is a need to consider more carefully than usual the individual person or family's circumstances, preferences, and values [10]. When implementing conditional recommendations, health providers need to allocate more time to shared decision-making and comprehensively explain the potential benefits and harms to people and their families [10]. It is becoming increasingly common for clinical guidelines to only include conditional recommendations, as guideline panels and developers recognize the importance of thinking holistically [43,44]. As evidenced by the COVID-19 pandemic, guideline developers also must balance the need for guidance with rapidly evolving research topics [43]. In this BPG specifically, conditional recommendations allow for guidance on an emerging topic (clinical practice in a digital health environment) while recognizing the need for nurses and health providers to consider the implications within their own health care context. Additionally, it has been argued that the implementation of all recommendations, including strong recommendations, depends on social and relational processes governing decision-making for individuals [43]. With this argument in mind, end users of all guidelines should think about contextual implications and the values and preferences of patients when implementing both strong and conditional recommendations.

A final limitation is that the authors only included studies published in English from 2017 onwards. They did not search for gray literature or search reference lists of included studies for further evidence due to timelines and feasibility. Therefore, it is possible that some additional studies were missed.

Conclusions

Digital health within the context of the clinical environment is an emerging topic. This BPG provides 4 evidence-based recommendations, along with good practice statements, implementation and evaluation, and monitoring resources. At the time of BPG development, no guidelines had been developed addressing evidence-based recommendations in this unique and growing area, especially as it relates to nurses and health providers. It is anticipated that this BPG can support nurses, other health providers, and health and academic organizations to make informed decisions about education and care related to digital health that can ultimately improve provider, patient, and system outcomes.

Acknowledgments

The authors would like to acknowledge the contributions of the 17 expert panel members for this BPG: Rob Beleno, Michelle Beyn (The Hospital for Sick Children), Rebecca Bliss (Hamilton Family Health Team), Elizabeth Borycki (University of Victoria), Margarita Cleghorne (Primacare Living Solutions Inc), Sandra Davidson (University of Calgary), Lorie Donelle (University of South Carolina, Western University), Alexander Hamilton (Kingston General Hospital), Tsz (Sally) Yee Ip (North York General Hospital, Holland Bloorview Kids Rehabilitation Hospital), Margery Konan (Michael Garron Hospital), Daile Moffat (Path2Care Inc), Sanaz Riahi (Ontario Shores Center for Mental Health Sciences), Tiziana Rivera (William Osler Health System), Tammy Rooke (CarePartners), Vaishali Sengar (Unity Health), Steve Sottile (Humber River Health), and Meredith Whitehead (Chatham-Kent Health Alliance). The authors would also like to acknowledge the external reviewers who provided feedback on the guideline before publication and additional Registered Nurses' Association of Ontario staff who assisted in creating this best practice guideline (BPG). The authors also acknowledge the leadership of the cofounder of this BPG, Humber River Health, and the significant contributions of expert panel cochair Vanessa Burkoski (Humber River Health), who passed away during the development of this BPG. The expert panel chose to dedicate the guideline to Vanessa Burkoski. Generative artificial intelligence was not used in any portion of the manuscript generation, or any portion of this work.

Funding

This work was funded primarily by the Government of Ontario. All work produced by the Registered Nurses' Association of Ontario is editorially independent from its funding source.

Data Availability

All data generated or analyzed during this review are included in this published article and its supplementary multimedia appendices. This information is also publicly available on the BPG website [4].

Abstract

Background: Recent advancements in digital health technologies have led to the accumulation of large volumes of unstructured text data, particularly in electronic health records. Given that nursing documentation frequently includes detailed descriptions of daily living activities and psychosocial contexts, existing medical natural language processing (NLP) tools may not be directly applicable without adaptation. Moreover, the integration of standardized nursing terminologies into NLP systems remains limited. Although NLP has the potential to support risk detection, information management, and care planning, its practical applications in nursing have not yet been systematically mapped.

Objective: This scoping review aimed to map the practical applications of NLP in nursing practice, with a specific focus on real-world clinical use, particularly for assessment, documentation, and interventions, and to identify the study characteristics, application domains, outcomes, and challenges.

Methods: Following the Joanna Briggs Institute methodology and PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines, a systematic search was conducted across PubMed, CINAHL, the Cochrane Library, Scopus, Embase, and Ichushi-Web in October 2023 and June 2025. The population-concept-context framework (population: nurses; concept: NLP applications; context: clinical settings) was used to guide study selection. Two independent reviewers screened 2889 unique records and reviewed the full texts of 72 studies. Data were descriptively synthesized and thematically classified.

Results: Six studies met the inclusion criteria, indicating that empirically evaluated applications of NLP in real-world nursing practice remain limited. NLP applications were categorized into three domains: (1) text summarization and generation, (2) information extraction and classification, and (3) real-time detection and screening. NLP was applied across multiple stages of nursing practice, including handovers, assessment, care planning, continuity of care, and patient safety management. Notably, NLP was used as a form of augmented intelligence to complement, rather than replace, nurses' clinical judgment and to support clinical decision-making. These findings also highlight a substantial gap between rapid technological advances and the limited implementation of NLP in real-world nursing practice.

Conclusions: This review highlights the substantial gap between rapid technological advances and the limited implementation of NLP in real-world nursing practice. NLP may help reduce manual review workload, support early risk identification, and facilitate individualized care planning in selected nursing contexts. However, direct empirical evidence regarding its effects on nursing workflows, nurses' clinical decision-making, and patient-level outcomes remains limited. Future research should prioritize real-world implementation studies and evaluate nurses' acceptance, adoption barriers, workflow integration, and the influence of NLP on clinical decision-making.

Introduction

Recent advances in information technology have resulted in the daily generation of vast amounts of health care–related data through digital systems, such as electronic health records (EHRs). EHRs comprise longitudinal data that are routinely collected in clinical settings, including patient demographic information, vital signs, clinical documentation, insurance claims data, patient-reported outcomes, and data obtained from home-based monitoring devices [1]. A previous review examined applications of the Internet of Things in health care and demonstrated that the integration of Internet of Things devices with cloud computing and AI technologies enables real-time remote monitoring and data-driven clinical insights, thereby contributing to transformative changes in health care delivery [2]. These technological developments have made the acquisition of clinical data easier. Consequently, the effective use of health care data in medical and nursing practice has become increasingly important, highlighting the need for advanced analytical approaches such as natural language processing (NLP).

NLP enables computers to analyze text and speech in natural language and transform unstructured information into structured data that can be computationally processed [3]. In health care, NLP has attracted increasing attention as a means of extracting meaningful information from text data in EHRs, and research in this field has expanded rapidly in recent years [4,5]. However, a substantial proportion of health care data, including EHRs, consists of unstructured text, which is estimated to account for approximately 80% of all medical data [6].

Although these textual data contain rich information about patients' conditions, clinical trajectories, and interventions, they are more difficult to analyze and use than structured data [7]. Specifically, nursing documentation generally describes patients' activities of daily living and psychosocial contexts in greater detail than medical diagnoses, which limits the direct applicability of existing medical NLP tools to nursing records. Existing NLP tools are primarily optimized for diagnostic terminologies and may not adequately support the analysis of nuanced expressions, domain-specific vocabulary, and clinical reasoning inherent in nursing documentation. Furthermore, variations in documentation styles across institutions and individual nurses pose a fundamental challenge to the standardization of NLP systems. The integration of standardized nursing languages—such as NANDA-International (NANDA-I), the Nursing Outcomes Classification, and the Nursing Interventions Classification—into EHRs enables the systematic documentation of nursing practice and facilitates the visualization and evaluation of nursing expertise and professional contributions [8].

Previous studies [9] have reported various applications of NLP in health care, including patient risk prediction and the analysis of clinical conversations. In nursing, NLP has also been applied to tasks such as symptom detection from home care records [10], hospitalization risk prediction based on nursing documentation [11], extraction of symptom-related information from EHRs [12], and fall risk prediction [13]. However, previous reviews have reported that most studies have focused primarily on technical aspects, such as disease classification and algorithm development, with limited attention to practical implementation for clinical interpretation and nursing assessment [12,14].

In recent years, the application of generative AI and large language models (LLMs) in health care has expanded rapidly, attracting considerable attention. However, a gap between technological advancement and real-world implementation has also been highlighted. According to a recent review [15], numerous LLM-related studies in health care have been published between 2023 and mid-2024. Nevertheless, most of these studies have focused on tasks such as question answering, with only limited research addressing clinical workflow support. Furthermore, concerns have been raised regarding the methodological rigor of many studies focusing on these emerging technologies [16]. Therefore, despite rapid advancements in AI, structural barriers to integration into clinical practice remain unresolved. Accordingly, rather than focusing on emerging technologies such as LLMs or ambient AI, this study adopts an implementation-oriented scoping review that prioritizes NLP applications implemented and evaluated within real-world nursing workflows.

Therefore, this scoping review aimed to comprehensively map how NLP has been applied in nursing practice, particularly to support nursing assessment, documentation, and interventions, with a focus on real-world clinical implementation. The present study also aimed to characterize previous research, identify application domains, and clarify reported outcomes and challenges. Specifically, we sought to (1) categorize the distinct types and roles of NLP approaches, (2) identify their impact across various stages of the nursing process, and (3) summarize the reported outcomes and barriers to implementation. By doing so, this study provides foundational insights for integrating "augmented intelligence" into professional nursing care.

Methods

Study Design

This scoping review followed the Joanna Briggs Institute methodology [17] and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines [18] (Checklist 1). This design was selected to map the existing evidence base and identify gaps in the evolving domain of NLP in nursing practice.

Search Strategy

The literature search was conducted using PubMed, CINAHL, the Cochrane Library, Scopus, Embase, and Ichushi-Web (Japan). The initial search was conducted on October 5, 2023. In the updated search, performed on June 13, 2025, the phrase "data mining" was added to enhance the search's sensitivity and comprehensiveness. The comprehensive search strategies for each database are tabulated in Multimedia Appendix 1. Equivalent search strategies were adapted for each database, as appropriate. The search strategy was designed to prioritize foundational NLP and data mining approaches with established evidence of clinical integration, reflecting the implementation-oriented scope of this review. Accordingly, the

XSL•FO
RenderX

review focuses on empirically evaluated applications within nursing workflows, rather than capturing the broad spectrum of emerging technologies such as generative AI or LLMs.

Eligibility Criteria

Using the Joanna Briggs Institute population–concept-context framework, the inclusion criteria were as follows: nurses (population), NLP applications in nursing practice (concept), and clinical settings (context). Eligible studies were peer-reviewed original articles in English or Japanese that described NLP applications in nursing practice (eg, assessment, documentation, or interventions). The eligibility criteria were specifically defined to identify studies describing the use of NLP within real-world nursing practice and clinical workflows. Studies were excluded if they (1) focused solely on technical model performance or diagnostic accuracy without clinical application or nursing involvement, (2) focused on physician-centered or other nonnursing applications without explicit involvement of nurses, or (3) were gray literature (eg, conference abstracts or proceedings) lacking sufficient methodological detail. Among studies addressing similar topics (eg, automated identification from clinical or radiology reports), only those that described applications within nursing-related clinical workflows (eg, assessment, documentation, or interventions) were included.

Study Selection

Two independent reviewers screened studies in 2 stages: screening of titles and abstracts, followed by full-text review. Disagreements were resolved through consultation with a third author. 19-2119-24

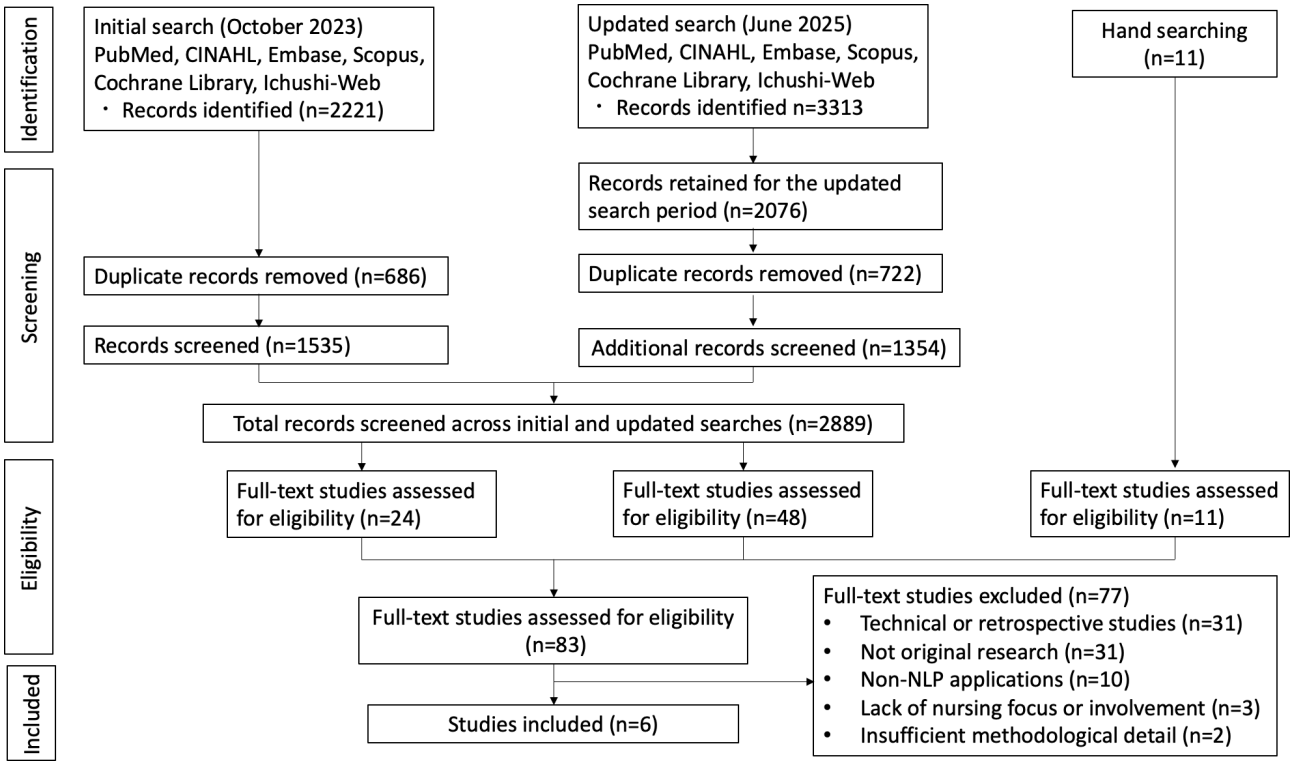
Data Extraction and Analysis

Data were extracted using a standardized form (see Multimedia Appendix 2) that included author, year, country, design, population, nursing practice domain, NLP techniques, performance metrics, human intervention points, and outcomes. The extracted data were descriptively synthesized. NLP techniques were categorized according to their methodological approach (eg, rule-based and machine learning), and applications were thematically classified according to clinical context (assessment, documentation, and interventions). Common themes among outcomes and challenges were aggregated.

Ethical Considerations

This study is a scoping review based on previously published literature and did not involve human participants. Therefore, ethics approval was not required in accordance with the authors' institutional policies.

Results



Study Selection Results

From the 1535 unique records in the initial search, 24 studies underwent full-text review, and 3 studies were included [19-21]. The updated search yielded an additional 1354 unique records and 48 full-text reviews, adding 3 more studies. Overall, 2889 unique records were screened, 72 full-text studies were reviewed, and 6 studies were included [19-24]. Hand searching the 11 references from relevant reviews identified no further studies.

As illustrated in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram, most of the records excluded during the title and abstract screening and the full-text review stages focused on the technical development or performance evaluation of NLP models and did not describe nursing practice or clinical workflow applications. The screening and selection process was conducted systematically and transparently based on predefined inclusion and exclusion criteria (Figure 1).

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of study selection.

Characteristics of Included Studies

Table 1 summarizes the characteristics of the included studies. The examined studies were published between 2012 and 2025 [19-24]. Four studies were conducted in the United States [19,21,23,24], 1 in the United Kingdom [22], and 1 in Taiwan [20]. The study designs included a pilot implementation study [20], retrospective and prospective implementation evaluation studies [19,21-23], and an observational implementation study [24].

Table . Characteristics of included studies.

Author (year)	Setting	Population	Study design	Data sources
Hunter et al [22], 2012	NICU[a]	Neonates	Prospective	EHR[b] (physiological data, notes)
Evans et al [19], 2016	Emergency department	Heart failure patients	Pre-post	EHR (physiological data, reports)
Tang et al [20], 2019	LTCF[c]	Older adults	Pilot	Nursing records
Boitano et al [21], 2023	Academic hospital	AAA[d]	Retrospective and prospective	Radiology reports (EHR)
Waltzman et al [23], 2024	Community	HAV[e] cases	Cross-sectional	Nursing notes
Nguyen et al [24], 2025	Integrated system	Patient safety cases	Observational	EHR notes

[a]NICU: neonatal intensive care unit.

[b]EHR: electronic health record.

[c]LTCF: long-term care facility.

[d]AAA: abdominal aortic aneurysm.

[e]HAV: health care–associated violence.

The primary data sources used across these studies consisted of unstructured text documented in EHRs, including clinical notes, nursing notes, incident reports, and handover records. The NLP techniques involved rule-based approaches [22-24], machine learning–based classification and prediction methods [19,20,23], and natural language generation [22]. Notably, all included studies implemented NLP as part of existing clinical systems involving nurses, rather than as a stand-alone technical intervention. For a more comprehensive description of study characteristics, including detailed setting information and specific data extraction methods, see Multimedia Appendix 3.

XSL•FO
RenderX

Categorization and Roles of Applied NLP Approaches

Overview

The applied NLP approaches were further categorized into 3 distinct types based on their clinical roles (Table 2). For a more comprehensive description of these approaches, see Multimedia Appendix 4.

Table . Application of natural language processing (NLP) in nursing practice.

Author (year)	NLP task (type)	Role of NLP	Direct impact on nursing	Key challenges
Hunter et al [22], 2012	Summarization	Automated summarization of clinical information	Handover and information sharing	Domain-specific (respiratory and cardiovascular)
Tang et al [20], 2019	Summarization	Care plan generation based on clinical data	Support for chronic disease management	Data privacy and security
Evans et al [19], 2016	Extraction	Identification of high-risk patients from EHR[a] data	Clinical decision support	Multicenter validation needed
Boitano et al [21], 2023	Extraction	Identification of patients with AAA[b] from radiology reports	Population health and nurse navigation	Dependence on explicit documentation
Waltzman et al [23], 2024	Extraction	Extraction of violent incidents from nursing notes	HAV[c] prevention and safety management	Manual review burden
Nguyen et al [24], 2025	Detection	Real-time triage of patient safety concerns	Telephone nursing triage	Limited infrastructure

[a]EHR: electronic health record.

[b]AAA: abdominal aortic aneurysm.

[c]HAV: healthcare-associated violence.

Type 1: Text Summarization and Generation

This approach involves generating standardized information from free-text nursing documentation to serve specific clinical purposes. One system [22] used natural language generation techniques to automatically produce standardized nursing shift summaries from EHR notes. This system reduced information loss during handovers and improved the quality of clinical information transfer. Similarly, another system [20] was developed to integrate historical nursing records and admission assessment documents to generate individualized nursing care plans. Notably, the system automatically retrieved up-to-date evidence, such as best practice guidelines, from web-based sources and incorporated this information into the generated plans, supporting the integration of evidence-based practice into routine nursing care.

Type 2: Information Extraction and Classification

This approach focuses on systematically extracting and identifying information related to specific diseases, risks, or events from unstructured nursing documentation or clinical reports. One study [19] applied a proprietary NLP algorithm to analyze comprehensive medical records, significantly improving the sensitivity for identifying patients with heart failure. Implementation of the system was associated with reductions in clinicians' diagnostic time and the 30-day mortality rate. Similarly, an existing NLP system [21] was used to automatically identify patients with abdominal aortic aneurysms (AAA) from radiology reports, enabling reliable referral of patients requiring follow-up and resulting in timely surgical interventions. Furthermore, an NLP-based method [23] extracted health care–associated violence (HAV) events from nursing notes. This facilitated high-accuracy identification of violent incidents that were frequently underreported in conventional incident reporting systems, thereby enhancing the visibility of workplace safety issues.

Type 3: Real-Time Detection and Screening

This approach involves the real-time analysis of free-text data to prioritize triage decisions or identify patient safety concerns. A real-time analysis system [24] examined appointment notes and triage documentation during outpatient scheduling to identify safety concerns. When detecting high-risk signals, nurses conducted immediate telephone follow-ups. This mechanism served as a clinical "safety catch" by supporting the early identification and follow-up of serious safety concerns. Furthermore, the system reduced the number of cases requiring manual review by approximately 80% (from a monthly average of 4215 to 705 cases), demonstrating improved operational efficiency.

Applications and Outcomes Across the Stages of the Nursing Process

The applications of NLP identified in the included studies were categorized according to the nursing process stages (Tables 1 and 2).

Information Sharing and Handover

For information sharing during shift changes, NLP-based automated summarization supported nurses by presenting patient information in a structured and comprehensible format. One study [22] reported that automatically generated nursing handover summaries were highly rated by clinicians, with 90% considered easy to understand, 70% considered accurate, and 59% considered helpful. These findings suggest that

XSL•FO
RenderX

NLP-mediated summarization may support effective information sharing during handovers.

Assessment and Discharge Planning

The use of NLP enabled early identification of high-risk patients and contributed to the acceleration of discharge support processes. An integrated NLP system [19] was used to analyze unstructured clinical notes alongside existing structured data (such as *International Classification of Diseases* codes), improving the sensitivity of patient identification for heart failure. This approach reduced clinicians' chart review time (10 vs 40 min), facilitating earlier assessment and intervention.

Care Planning

NLP supported the more rapid development of individualized care plans. One study [20] reported a reduction in the time required for care planning from 7 to 4 days (a 42.8% improvement) and an increase in the acceptability of these plans from 39% to 78%. The system also supported more consistent care planning, particularly among less experienced staff.

Follow-Up and Continuity of Care

Continuous system-based monitoring optimized nurse navigation and enabled proactive outreach. A large-scale analysis [21] identified 6495 patients with AAA from 6.3 million radiology reports and facilitated 29 follow-up outpatient visits for patients whose surveillance had lapsed, as well as 4 surgical interventions for 3 patients. These outcomes helped improve adherence to guideline-recommended surveillance.

Safety Management and Surveillance

NLP enhanced the visibility of safety threats, which were often overlooked by conventional reporting systems. Using an NLP-assisted approach [23], HAV events were extracted from nursing notes with a sensitivity of 96.8%. In addition, a real-time safety screening [24] facilitated the identification of serious concerns and reduced the number of cases requiring manual review by approximately 80% (from a monthly average of 4215 to 705 cases), demonstrating improved operational efficiency.

Outcomes and Challenges of NLP Implementation

Across the included studies, the primary reported benefits of NLP implementation included reduced nursing workload, enhanced identification of specific risks or target populations, and support for nurses' clinical decision-making (Table 2). Specifically, the studies reported standardized handovers and reduced information loss [22], earlier identification of high-risk patients and acceleration of discharge planning [19], improved efficiency of care plan development and integration of up-to-date clinical knowledge [20], proactive follow-up of patients with AAA who have not received recommended surveillance [21], increased visibility of HAV events [23], and facilitation of concern identification with a substantial reduction in nurses' time spent on manual record review [24]. Notably, these functions did not replace nurses' decision-making; rather, NLP operated as a form of augmented intelligence that complemented professional judgment and supported the translation of insights into appropriate nursing interventions.

All included studies reported notable challenges and limitations. Some studies were conducted within a single institution [19], emphasizing the need for external validation across diverse clinical settings. Studies using rule-based or keyword-dependent approaches [21,22,24] reported that inaccuracies in documentation and variability in language use resulted in false positives or missed cases. To mitigate these technical limitations and the risk of erroneous outputs, the included studies implemented human-in-the-loop mechanisms to safeguard clinical judgment. These mechanisms functioned as important safeguards against algorithmic rigidity and potential errors in automated classification, ensuring that qualified clinicians, such as specialist nurses or nurse navigators, retained responsibility for clinical decisions by reviewing and validating NLP outputs (Table 2). Additionally, several studies emphasized that translating NLP-derived information into actual clinical interventions necessitated the availability of dedicated nursing personnel, such as nurse navigators or specialized teams [21,23]. Overall, these findings suggest that NLP complements rather than replaces nursing judgment. By structuring narrative data, NLP may facilitate informed decision-making. Therefore, future NLP systems should be designed as robust human-in-the-loop tools that empower nurses as final arbiters of clinical safety, ensuring seamless integration into nursing workflows.

Discussion

Summary of Findings

In this scoping review, only 6 studies [19-24] met the inclusion criteria, highlighting a substantial implementation gap between the rapid advancement of NLP technologies and their integration into real-world nursing practice. The limited number of eligible studies is an important finding in itself. Rather than focusing solely on whether NLP can technically process nursing documentation, this review highlights the broader question of why implementation-oriented NLP research in nursing remains so limited. The findings of this review suggest that this implementation gap reflects interrelated technical, organizational, and professional and cultural barriers to implementation.

Factors Contributing to the Implementation Gap

Technical Barriers

Nursing documentation often consists of heterogeneous free-text narratives describing patients' health status, symptoms, functional status, and other contextual information, which makes standardization challenging [8,14]. Standardized nursing terminologies are therefore fundamental to ensuring the comparability, interoperability, and secondary use of nursing data [8]. However, a recent review found that the use of standardized nursing terminologies in nursing NLP research remains limited [14]. Furthermore, a recent study reported that nurses perceived institutional and technical barriers to implementing NANDA-I, Nursing Interventions Classification, and Nursing Outcomes Classification in clinical practice [25]. These limitations in the adoption of standardized nursing terminologies may hinder the development and external validation of NLP systems for nursing documentation, thereby

XSL•FO
RenderX

limiting their implementation and generalizability. In addition, the limited representation of standardized nursing terminologies in NLP training datasets may constrain the ability of NLP models to recognize nursing-specific concepts, relationships, and clinical reasoning patterns.

Organizational Barriers

EHR systems continue to face challenges related to data access, interoperability, privacy protection, and data governance [1,26]. Access to nursing record datasets may also be restricted by institutional ethics review requirements, data-use approval processes, and concerns regarding the secondary use of sensitive clinical documentation. Similar implementation barriers, including inadequate technical support, poor system integration, and usability issues, have also been identified in a scoping review of EHR implementation [27]. Furthermore, insufficient involvement of end users during the planning, development, and implementation of EHR systems has been recognized as a common implementation barrier [27]. These organizational challenges may hinder the integration of NLP into routine nursing workflows and limit its implementation in clinical practice.

Professional and Cultural Barriers

Although physician-centered structured data have been the primary focus of EHR and NLP research, nursing documentation may have been underused. This imbalance may partly explain why implementation studies of NLP in nursing remain limited. Consistent with this concern, a previous review [28] found that nurses' involvement was limited, particularly during the early phases of AI development, and that ethical considerations related to the implementation and use of AI in nursing received limited attention. In addition, publication bias may have contributed to the underreporting of unsuccessful implementation efforts or negative findings, thereby skewing the available evidence toward successful cases. Taken together, these professional and cultural barriers may help explain why implementation-oriented NLP research in nursing remains limited. Addressing these barriers may require involving nurses as coinvestigators throughout the development and evaluation of NLP systems to ensure that these technologies are aligned with nursing practice.

Implications for Implementation

Unlike previous reviews, which have predominantly focused on the technical aspects of NLP or broader implementation and ethical issues related to AI in health care [12,14,29], this review examined how NLP has been integrated into nursing workflows and the extent to which nurses are involved in these systems in real-world clinical settings. Although recent interest has shifted toward LLM-based applications, empirical evidence regarding the implementation of these emerging technologies remains limited. Consistent with previous comprehensive reviews [28], there is limited empirical evidence regarding the effects of NLP on clinical outcomes, nurses' decision-making, and integration into routine nursing practice. This pattern is also evident in more recent research. For example, a recent review [15] reported that only 12.5% of 415 studies using advanced LLMs focused on clinical workflow support, whereas most applications addressed clinical decision support or patient information support. Similarly, although ambient AI technologies have recently received substantial attention, peer-reviewed empirical evidence regarding their implementation in nursing practice remains limited. Notably, although some studies have reported usability or perceived helpfulness [22], nurse acceptance and implementation barriers have rarely been examined explicitly, highlighting another important gap in the current evidence base. These findings suggest that the successful implementation of NLP in nursing depends not only on technological performance but also on organizational support, professional engagement, and well-defined implementation processes.

NLP as Augmented Intelligence

Previous reviews have noted that health care NLP has primarily emphasized algorithm development, data extraction, and classification tasks, with relatively limited attention to supporting nurses' judgment, decision-making, and care processes [12,14]. Specifically, one review [12] reported that many studies primarily used NLP for classification, whereas an integrative review [14] highlighted the need for improved evaluation, standardization, and broader application of NLP in nursing. Building on these observations, this review shifted the focus from technical accuracy alone to empirical evidence of how NLP is used in nursing practice and how it may support clinical decision-making. The included studies suggest that NLP may reduce manual review workload, improve patient identification, and facilitate clinical decision-making in selected nursing contexts [19,21,24]. Collectively, these findings indicate that NLP may support clinical workflows by functioning as an analytical tool and a decision support resource. However, direct empirical evidence regarding patient outcomes remains limited.

These findings suggest that NLP should not be conceptualized as a technology that fully automates nurses' clinical judgment. Rather, it may be better understood as a form of augmented intelligence that complements and supports cognitive processes in nursing practice. In particular, NLP may support clinical reasoning by processing large volumes of unstructured data during the early stages of assessment and information processing [30]. This perspective aligns with the principle that clinical decision support systems should be integrated into clinical workflows while preserving professional judgment [31]. The reported usefulness of automatically generated summaries [22] is consistent with this perspective and with the broader concept of the convergence of human and artificial intelligence [32].

Previous studies have identified several challenges associated with clinical decision support systems, including omission and commission errors [33] and concerns regarding data security and patient privacy [20]. As NLP becomes increasingly incorporated into clinical decision support and nursing workflows, related risks, including automation bias, warrant careful consideration. However, empirical evidence on how these challenges affect the implementation of NLP in nursing practice remains limited.

Accordingly, future implementation efforts should focus on the safe and responsible integration of NLP into nursing practice. Because NLP applications process sensitive personal health information, robust privacy protection and data security are essential [20,34,35]. Previous studies have also emphasized the

XSL•FO
RenderX

importance of explainability and responsible AI implementation [36]. Building on these considerations, future research should explore strategies to improve AI literacy among nurses and thereby facilitate the responsible implementation of NLP in clinical practice.

Taken together, these findings suggest that NLP should be considered not merely as a technical tool but as part of clinical systems that involve nurse engagement. This perspective is conceptually aligned with the Non-Adoption, Abandonment, Scale-Up, Spread, and Sustainability framework [26], particularly regarding NLP adoption, integration into routine clinical workflows, and long-term sustainability in nursing practice. The technical, organizational, and professional barriers identified in this review may represent key challenges to the adoption, routine integration, and long-term sustainability of NLP in nursing practice. This review, therefore, provides an implementation-oriented perspective that may guide future research and support the integration of NLP into nursing practice.

Limitations

This scoping review has several limitations. First, the literature search was restricted to studies published in English and Japanese, potentially introducing language bias. Second, the number of databases searched was limited, and gray literature, including doctoral dissertations, conference proceedings, and unpublished reports, was excluded. Consequently, some relevant studies may have been missed. Furthermore, as this review specifically focused on NLP applications in nursing practice, it excluded studies that did not explicitly involve nurses in clinical workflows (eg, physician-centered applications). Future reviews should incorporate broader database coverage and gray literature to provide a more exhaustive overview of the field. Third, the number of included studies was small, reflecting the limited implementation of NLP in nursing practice and the early stage of implementation-oriented research in this field. Accordingly, this review provides a map of current research trends rather than definitive conclusions, and further empirical studies are warranted as the field evolves. Fourth, the search strategy was predominantly designed to capture foundational NLP and data mining techniques. Therefore, it may not have fully captured the most recent studies focusing on generative AI and ambient AI technologies, which have proliferated rapidly in recent years. Given the recent surge in studies using these technologies for nursing documentation, summarization, and care planning, this review's findings may not fully reflect this emerging body of work. Future studies should compare traditional NLP approaches with newer generative AI technologies to explore their distinct impacts on nursing practice. Fifth, a geographic bias exists, as the included studies were conducted in a limited number of regions, specifically the United Kingdom, the United States, and Taiwan. Consequently, the findings may have limited generalizability to diverse nursing environments with different health care systems and cultural contexts. Finally, in accordance with the methodological nature of a scoping review, this study did not include a formal appraisal of the methodological quality or the risk of bias of the included studies. Therefore, caution should be exercised when interpreting the findings. Future research should incorporate systematic quality assessment to strengthen the evidence base and validate the conclusions drawn.

Conclusions

This scoping review suggests that NLP may support nursing practice by extracting and generating clinically relevant information from unstructured nursing-related text. However, empirical evidence regarding its implementation in real-world nursing practice remains limited. Rather than replacing professional judgment, NLP may function as a form of augmented intelligence that supports nurses' clinical decision-making. In selected nursing contexts, NLP may help reduce manual review workload, facilitate early risk identification, and support information processing. Nevertheless, direct empirical evidence regarding its effects on nursing workflows, nurses' clinical decision-making, and patient-level outcomes is limited. Future research should examine nurses' acceptance, adoption barriers, and implementation processes in real-world clinical settings.

Although previous studies have often focused on system development and technical performance, future research should prioritize implementation-oriented evaluations and assess how NLP influences nurses' clinical decision-making in practice. To support the responsible integration of AI technologies into nursing practice, nurses may require sufficient AI literacy to critically appraise and interpret AI-generated outputs. Developing this knowledge and these skills may help nurses use AI technologies while maintaining professional judgment in an increasingly digital health care environment.

The principal contribution of this review is to identify the substantial gap between rapid technological advances and the limited implementation of NLP in real-world nursing practice, rather than to establish the effectiveness of NLP.

Acknowledgments

We express our sincere gratitude to all contributors to this study. We also thank Editage for their English language editing services.

During the preparation of this manuscript, the authors used ChatGPT (OpenAI) and Gemini (Google) for English translation and to improve the manuscript's readability. The authors take full responsibility for the content.

Funding

This study did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Abstract

Background: Technologies such as virtual reality (VR) and augmented reality (AR) have been increasingly incorporated into nursing education to support the development of cognitive, psychomotor, and behavioral competencies. In midwifery, immersive environments offer opportunities to simulate high-risk or low-frequency clinical scenarios, strengthening students' confidence and preparedness for professional practice. However, there is still significant variability in how VR and AR are pedagogically implemented, with limited understanding of their theoretical grounding, instructional design, and educational outcomes.

Objective: This systematic review aimed to synthesize and critically evaluate the characteristics of educational programs using VR and AR to develop competencies among nursing and midwifery students and professionals.

Methods: This review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 and Synthesis Without Meta-Analysis (SWiM) guidelines and was registered in PROSPERO (International Prospective Register of Systematic Reviews). A comprehensive search was conducted in August 2024 across PubMed, Web of Science, Scopus, and Cumulative Index to Nursing and Allied Health Literature (CINAHL) databases. Eligible studies were experimental, quasi-experimental, or observational, and involved undergraduate or postgraduate students in nursing, obstetric nursing, or midwifery, as well as certified midwives or nurse-midwives. Two independent reviewers conducted screening, data extraction, and quality appraisal using Joanna Briggs Institute (JBI) tools and the Medical Education Research Study Quality Instrument (MERSQI) scale. Data were synthesized narratively according to predefined thematic categories.

Results: Four studies published between 2021 and 2024 met the inclusion criteria, encompassing 634 participants (360 midwifery students and 274 midwives or nurse-midwives). Two randomized controlled trials and 2 quasi-experimental studies were included. Interventions used VR in 3 studies and AR in one, simulating scenarios such as normal and complicated childbirth, neonatal resuscitation, and emergency obstetric procedures. Most interventions focused on developing technical competencies, while one also addressed teamwork and communication. Only 2 studies explicitly reported theoretical or pedagogical frameworks, and 2 mentioned alignment with the INACSL Healthcare Simulation Standards of Best Practice. Structured briefing or debriefing was rarely described. All studies assessed learning outcomes (Kirkpatrick level 2), and 3 included participants' satisfaction (level 1). Methodological quality, measured by MERSQI, ranged from 10.0 to 14.5, with a mean score of 12.9 (SD 2.0), indicating moderate to high quality.

Conclusions: Evidence suggests that VR and AR can enhance learning in obstetric nursing and midwifery education by providing safe, experiential, and interactive learning environments. However, the limited use of theoretical frameworks and structured instructional design highlights the need for more pedagogically grounded interventions. Future research should prioritize the integration of learning theories, validated assessment tools, and best-practice simulation standards to strengthen the educational impact and curricular integration of immersive technologies in nursing and midwifery education.

Introduction

Background

The integration of virtual reality (VR) and augmented reality (AR) has demonstrated promising effectiveness in health education, particularly in the development of cognitive, psychomotor, and behavioral competencies [1-3]. These technologies enable immersion in interactive 3D environments, allowing for the safe practice of complex procedures and the visualization of anatomical and physiological phenomena that are difficult to observe in real clinical settings [1,4]. When applied in a planned manner and supported by clear educational objectives, they foster clinical reasoning, decision-making [5], and student engagement [6].

Nursing education has explored the potential of these technologies across different clinical areas [2], and obstetric nursing and midwifery, in particular, has benefited from the ability to simulate complex clinical scenarios, contributing to the development of technical and nontechnical competencies essential for safe care of women throughout the perinatal period [7,8].

Despite advances in research, there remains significant variability in how VR and AR are implemented within nursing education programs, reflecting the diversity of pedagogical approaches and levels of curricular integration reported in the literature [5,9,10]. Given the inherent complexity of immersive environments, challenges related to students' cognitive load may be exacerbated, particularly when the degree of immersiveness and the instructional design are not aligned with the learning objectives [11,12]. Therefore, it is relevant to understand how immersive technologies have been applied in obstetric nursing and midwifery education and to what extent their implementation is grounded in solid pedagogical and theoretical principles [13,14].

In this context, a systematic synthesis of the literature is essential to identify how VR and AR have been integrated into obstetric nursing and midwifery education, evaluating the presence of theoretical foundations, instructional models, and assessment strategies that guide their pedagogical application. This analysis contributes to the development of evidence-based educational practices for the integration of these technologies into nursing and midwifery education.

Objective

This systematic review aimed to synthesize and critically evaluate the characteristics of educational programs that use VR and AR technologies to develop obstetric competencies among nursing and midwifery students and professionals.

Methodology

Study Design

This systematic review was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; Checklist 1) guidelines and the Cochrane Handbook for Systematic Reviews of Interventions [15,16]. The study protocol was developed by the research team and registered in PROSPERO (International Prospective Register of Systematic Reviews; registration number: CRD42025635292). No ethical approval was required.

Information Sources and Search Strategy

The search was conducted on August 14, 2024, in the following databases: PubMed, Web of Science, Scopus, and Cumulative Index to Nursing and Allied Health Literature (CINAHL).

The search strategy was structured based on the PIO framework (Population, Intervention, Outcome). The population included undergraduate and postgraduate students in nursing, obstetric nursing, or midwifery, as well as practicing midwives and nurse-midwives. The interventions comprised educational programs using VR and AR as pedagogical tools for developing clinical competencies in obstetrics. The outcomes of interest encompassed theoretical and pedagogical models, instructional design, assessment strategies, and competencies addressed by the interventions.

The terms were organized into 3 conceptual blocks and adapted to the syntax of each database. No filters were applied regarding language, publication date, or document type. The complete search strategy is presented in Multimedia Appendix 1.

Eligibility Criteria

Eligible studies were primary research with experimental, quasi-experimental, or observational designs, published in peer-reviewed journals. The population included undergraduate nursing students, obstetric nursing and midwifery students, postgraduate obstetric nursing and midwifery students, and certified midwives and nurse-midwives.

Interventions were required to involve extended reality (XR) technologies, operationalized in this review as VR or AR applications used for clinical simulation with active learner interaction. VR interventions were eligible when they involved head-mounted or headset-based immersive delivery and first-person interaction within a simulated clinical environment, such as manipulating virtual objects, selecting or performing clinical actions, or responding to scenario-based clinical cues. AR interventions were eligible when they involved digital overlays integrated into the real-world environment, accessed through mobile or wearable devices, and required interaction with virtual elements as part of the simulated clinical activity. Passive 360-degree video, noninteractive video-based learning, desktop-based simulation, standard e-learning, mobile applications without AR overlays or immersive delivery, physical simulations without VR or AR integration, training conducted outside educational contexts, and studies in general nursing without a specific focus on obstetric or immediate neonatal care were excluded (Multimedia Appendix 1).

Study Selection Process

The search results were imported into Rayyan (Qatar Computing Research Institute Hamad Bin Khalifa University) [17]. After duplicate removal, 2 reviewers (MLF and APM) independently and blindly screened the studies across 3 successive phases: titles, abstracts, and full texts. Interrater reliability was assessed using the final subset of 33 records evaluated at the full-text stage. Agreement was reached for 28 of the 33 decisions

XSL•FO
RenderX

(84.8%), yielding a Cohen kappa coefficient of 0.52, which indicates moderate agreement. Each reviewer systematically recorded the reasons for exclusion using a structured format based on the eligibility criteria. Discrepant decisions were initially discussed between the 2 reviewers to reach consensus. When consensus was not possible, the studies were referred to 2 additional reviewers (AC and CSC), who independently reassessed them using the same criteria. Final inclusion or exclusion decisions were made after discussion among the reviewers, considering the predefined methodological criteria and the additional assessments provided.

Most disagreements involved borderline eligibility decisions related to the operational definition of immersive technology and clinical simulation. In particular, discrepancies concerned the distinction between fully immersive VR and 360-degree video or other noninteractive formats, the minimum level of user interaction required for inclusion, and whether the intervention involved scenario-driven simulation within an obstetric or immediate neonatal care context. These issues were resolved by applying the predefined eligibility criteria, which required immersive VR or AR with active learner interaction and a specific focus on obstetric or immediate neonatal care education.

Data Extraction

Data extraction was conducted independently by 2 reviewers (MLF and APM) using a standardized form, specifically developed for this review based on the study objectives. The form was pilot-tested on 2 included studies, allowing adjustments to ensure clarity and consistency in data collection.

Information was extracted regarding study characteristics, population, and educational intervention. These data included: study title, authors, year of publication, and country; study design; participants' professional background and educational level; learning theory adopted; instructional design models; the Bloom Revised Taxonomy domains targeted by the intervention [18]; Kirkpatrick levels used for evaluating the interventions [19]; type of clinical environment and simulated context; technical and nontechnical skills addressed; data collection methods and assessment instruments (type, content, validity, and timing); and data analysis methods. Regarding technological features, we extracted system-level characteristics related to immersive delivery, including device type and interaction modality with virtual elements. Additional data included supporting educational materials, use of complementary teaching strategies, duration of the simulation, reported implementation challenges, funding sources, and outcomes related to knowledge, skills, attitudes, and learning experience. Discrepancies were resolved by consensus or by consulting a third reviewer (CSC). The data were organized using Microsoft Excel spreadsheets.

Risk-of-Bias and Methodological Quality Assessment

Risk of bias was assessed independently by two reviewers (MLF and APM) using the Joanna Briggs Institute (JBI) critical appraisal tools [15], applied according to the methodological design of each included study.

For randomized controlled trials (RCTs), the revised JBI checklist comprising 13 items was used [20]. These are organized into 5 core domains: participant selection and allocation, delivery of the intervention or exposure, assessment, detection and measurement of outcomes, participant retention, and statistical conclusion validity.

For quasi-experimental studies, the revised JBI checklist with 9 items was applied [21], covering the following domains: temporal-procedural bias, selection and allocation bias, confounding bias, bias in the delivery of the intervention or exposure, bias in the assessment, detection and measurement of outcomes, and bias related to participant retention.

Each item in the checklists was classified as "yes," "no," "unclear," or "not applicable," in accordance with the guidance provided in the respective tools. Disagreements between reviewers were resolved by consensus.

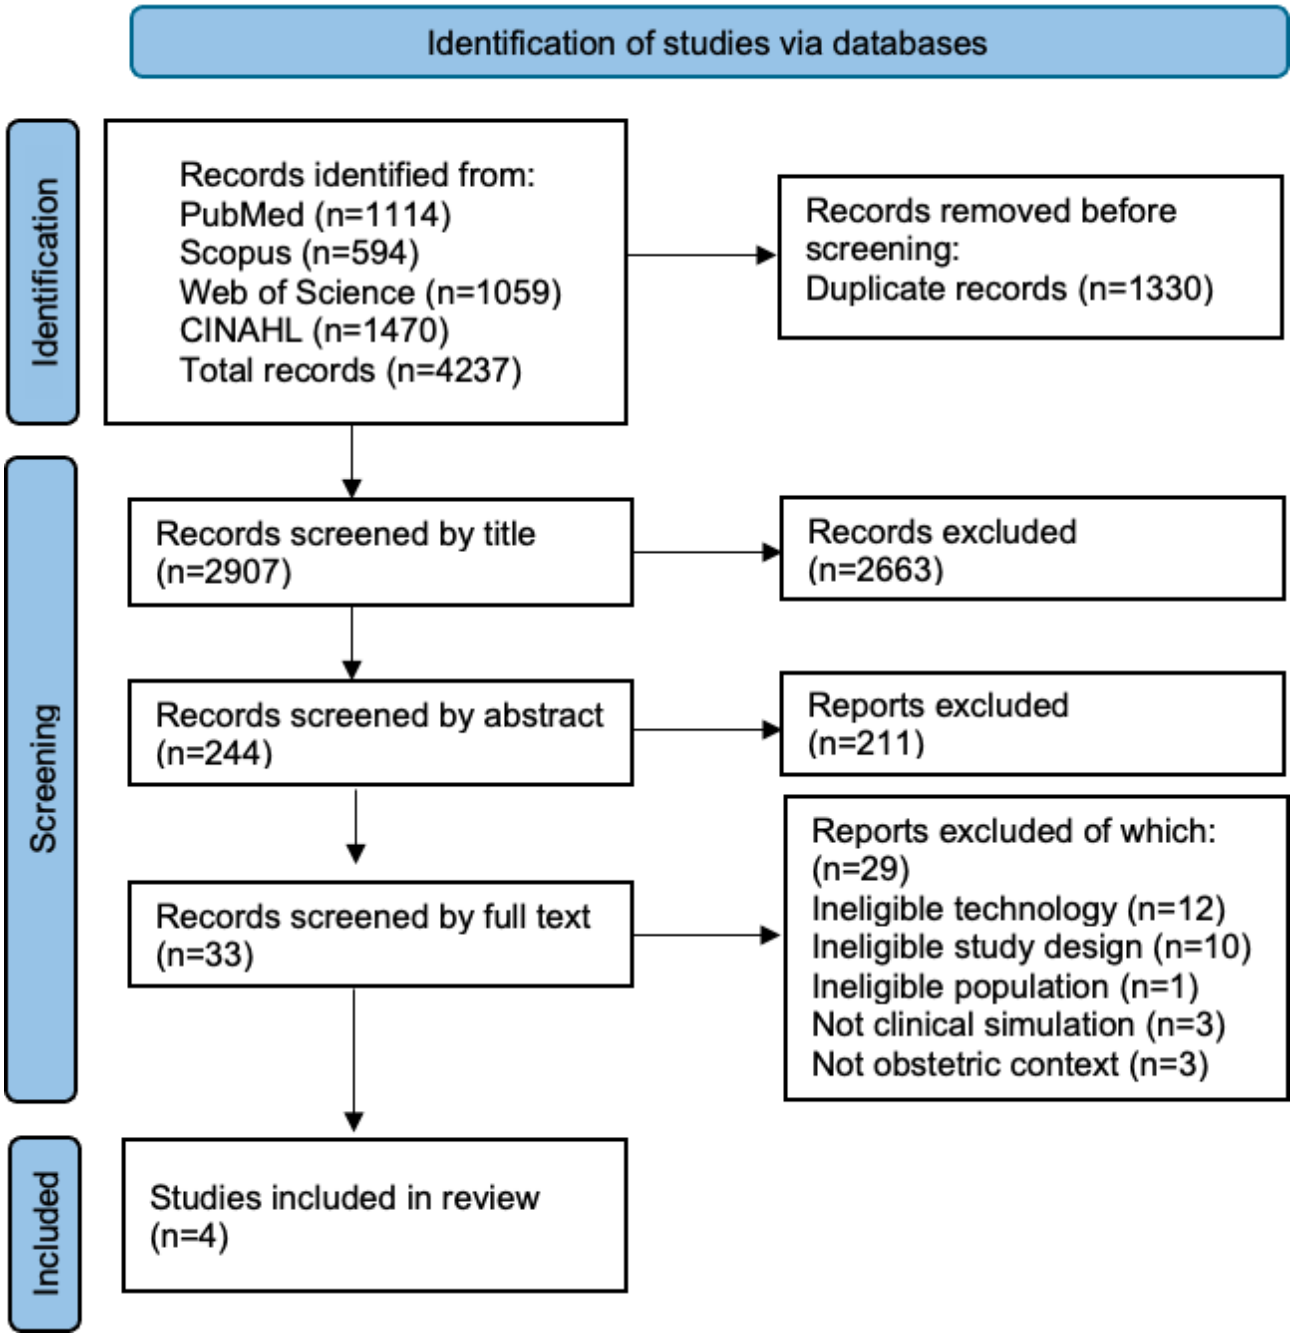
In addition, the Medical Education Research Study Quality Instrument (MERSQI) [22] was used to assess the methodological quality of studies from the perspective of health professions education research. The instrument comprises 6 domains: study design, sampling, type of data, validity of instruments, statistical analysis, and educational outcomes. Each domain has a maximum score of 3 points, with the total score ranging from 5 to 18 points.

Uncertainties and disagreements were addressed and resolved through consensus. Studies were not blinded with regard to authorship, institutional affiliation, or publishing journal.

Data Synthesis Strategy

In line with the review objectives, a narrative synthesis approach was planned a priori and conducted following the Synthesis Without Meta-Analysis (SWiM) reporting guidelines [23]. A meta-analysis was not performed due to substantial heterogeneity across the included studies, including differences in intervention characteristics (VR vs AR), study designs, outcome measures, assessment instruments, and timing of evaluation. In addition, quantitative data were reported inconsistently, with some studies presenting means and SDs, while others reported percentages or did not provide sufficient data, further precluding meaningful statistical pooling.

The extracted information was organized into predefined thematic categories, including study characteristics, educational interventions, theoretical and pedagogical foundations, technologies used, assessment instruments, and main findings. The results were presented descriptively and analytically, allowing comparisons based on shared methodological elements. Supporting tables and summary charts were developed to facilitate comparative analysis, and quantitative evidence was summarized where appropriate. Findings were synthesized by grouping results according to outcome domains (knowledge, skills, attitudes, and learning experience) and by examining the direction and consistency of results across studies.



Results

The database search retrieved 4237 records. After the removal of 1330 duplicates, 2907 titles were screened, resulting in 244 records selected for abstract assessment. Of these, 33 full-text articles were evaluated, and 4 studies were included in the

XSL•FO
RenderX

review. Figure 1 presents the PRISMA flow diagram of the selection process.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the present study.

Characteristics of the Studies

The 4 included studies [24-27] were published between 2021 and 2024 and represented diverse geographical and educational contexts. Three studies involved undergraduate midwifery students [24-26], while one multicenter study included certified midwives and nurse-midwives working in maternity settings [27]. Overall, the review comprised 634 participants, including 360 midwifery students and 274 practicing midwives or nurse-midwives.

The methodological designs included 2 RCTs: one with 6-month follow-up comparing the use of VR with instructional video or digital guide [27], and another comparing VR with low-fidelity clinical simulation [25]. In addition, one quasi-experimental study with a control group compared VR with traditional teaching methods [26], and another quasi-experimental study without a control group used pre- and postintervention measures to evaluate the impact of AR across different simulated clinical scenarios [24]. Detailed study characteristics are presented in Table 1.

Table . Study characteristics.

Study (year)	Country	Type of study	Population and sample	Study objectives	XR[a] Type	Simulation scenario
Vogel et al (2024) [24]	Germany	Quasi-experimental, without a control group, (pre- and posttest design)	Midwifery students, n=133	To investigate whether AR[b] simulation training influences midwifery students' subjective perceptions of knowledge, confidence, and practical skills in emergency situations.	AR	Emergency tocolysis, preparing a pregnant woman for cesarian section, neonatal resuscitation
Öner and Turfan (2024) [25]	Türkiye	RCT[c], (posttest only design)	Midwifery students, n=92	To compare the impact of VR[d] simulation with low-fidelity simulation in teaching newborn care to obstetric nursing students.	VR	Initial care of the newborn
Zhao et al (2024) [26]	China	Quasi-experimental, with a control group, (posttest only design)	Midwifery students, n=135	To evaluate the effect of case-based learning method with VR simulation technology on midwifery courses.	VR	Eutocia (normal birth), dystocia, umbilical cord prolapse, and neonatal asphyxia and resuscitation
Umoren et al (2021) [27]	Nigeria and Kenya	RCT, 6 months follow-up	Midwives and nurse-midwives, n=274	To assess the impact of VR simulations using electronic Helping Babies Breathe or video for the maintenance of neonatal resuscitation skills in health care workers in resource-scarce settings.	VR	Routine newborn care, initial resuscitation, and prolonged resuscitation with positive pressure ventilation

[a]XR: extended reality.

[b]AR: augmented reality.

[c]RCT: randomized controlled trial.

[d]VR: virtual reality.

Description of the Educational Intervention

All 4 studies [24-27] investigated educational interventions that used clinical simulation mediated by XR technologies, with the aim of developing clinical competencies in obstetric or immediate neonatal care.

The simulated clinical contexts included: preparation of emergency tocolytics and preparation of the pregnant woman for cesarean section [24]; eutocic delivery, dystocia, and umbilical cord prolapse [26]; immediate newborn care [25]; and neonatal asphyxia and resuscitation [24,26,27]. Neonatal care was a common component in all 4 programs analyzed, consistently simulated in the context of immediate newborn care, immediately after birth.

Of the 4 studies included, 3 presented multiple simulation scenarios within the same intervention using VR [26,27] or AR [24]. None of the included studies provided detailed information about the physical simulated environment used in the interventions.

Technology Used

The included interventions used technically distinct XR configurations, with VR being more common than AR. Based on the operational definition used in this review, 3 studies were classified as VR because they used headset-based immersive delivery and first-person task-based interaction within simulated clinical scenarios [25-27]. Two of these used head-mounted display (HMD)–based VR with handheld controllers [25,26], while one used a low-cost smartphone-based HMD with a VR application [27]. One study was classified as AR because it used a smartphone-based marker system to overlay and manipulate virtual elements within the real-world environment [24]. The main technical characteristics of the interventions are summarized in Table 2.

Across studies, interaction was generally described as first-person and task-based, requiring participants to perform

XSL•FO
RenderX

clinical actions or manipulate virtual elements within simulated obstetric or neonatal scenarios [24-27]. However, the level of interactivity was not consistently detailed. In particular, information on free navigation, branched decision-making, customization of the virtual environment, and learner control was absent or limited.

Reporting of exposure and technical design features was also incomplete. Although some studies reported session duration or total usage time, the number of sessions and degree of learner autonomy were often unclear. Similarly, visual fidelity, spatial realism, software licensing, reusability, and open-access availability were not described. This limited reporting restricts comparison of the technological complexity and pedagogical affordances of the XR systems used across studies.

Table . Technical characteristics of XR[a] interventions.

Study	XR type	Device (hardware)	Software	Interaction	Duration and exposure	Presence and usability	Adverse effects
Vogel et al (2024) [24]	AR[b]	Smartphone +marker	Heb@AR	Active task-based interaction through manipulation of the virtual elements	Not reported	Not reported	Not reported
Öner and Turfan (2024) [25]	VR[c]	HMD[d] (Oculus Quest)+handheld controllers	Unity-based VR simulator	Active task-based interaction through manipulation of the virtual environment	Up to 10 minutes per session	Presence assessed; Usability not reported.	Dizziness and nausea
Zhao et al (2024) [26]	VR	HMD+handheld controllers	CBL-VR[e] platform	Active task-based interaction through manipulation of the virtual environment and feedback	Not reported	Not reported	Mild cybersickness (not quantified)

Theoretical and Pedagogical Frameworks

Two studies [25,26] reported an explicit pedagogical or theoretical basis for their immersive simulation interventions. Zhao et al [26] integrated case-based learning (CBL) with VR simulation to support clinical reasoning, while Öner and Turfan [25] referred to the Jeffries Simulation Theory [28] as a framework for the design, implementation, and evaluation of the simulation. The remaining studies did not report an explicit theoretical model or instructional framework [24,27].

Across the included studies, the interventions primarily targeted the development of technical competencies related to obstetric or neonatal care, particularly procedures associated with childbirth, obstetric emergencies, immediate newborn care, and neonatal resuscitation [24-27]. Nontechnical or behavioral competencies were less frequently addressed; only Zhao et al [26] explicitly included communication, teamwork, and clinical decision-making.

Although Bloom's Taxonomy [18] was not explicitly used by the primary studies, the described activities could be mapped mainly to the cognitive and psychomotor domains. All studies involved the application of knowledge in simulated clinical contexts and the performance of obstetric or neonatal skills [24-27]. Higher-order cognitive processes, such as case analysis and decision-making, as well as affective elements related to teamwork, were identified only in Zhao et al [26].

Similarly, none of the studies explicitly adopted the Kirkpatrick model [19] as an evaluative framework. However, based on the reported outcomes, all studies assessed level 2 outcomes, including knowledge, practical skills, and/or attitudes. Three studies also assessed level 1 outcomes, such as satisfaction or perceptions of the learning experience [24-26]. No study evaluated level 3 outcomes or level 4 outcomes.

Reporting of instructional design and simulation best-practice components was limited. None of the studies described the use of a structured instructional design model, although 2 cited the

XSL•FO
RenderX

Healthcare Simulation Standards of Best Practice [29] as a guiding reference for simulation development and implementation [24,25]. Structured pedagogical briefing was not clearly reported. Instead, most studies described technical orientation to the technology, such as guidance on the use of VR or AR devices [24,26,27].

Debriefing was also inconsistently described. Only Öner and Turfan [25] reported a structured debriefing process, supported by the Jeffries Simulation Theory [28] and based on audiovisual review of the simulation. Other studies described less structured forms of feedback, including automated feedback provided by the application [24], feedback during the activity [26,27], or facilitator-mediated group feedback after the activity [26].

In all included studies, simulation was conducted individually. In one study, the facilitator was described as playing an active role providing guided instruction during the simulation [25]; in another, the activity was conducted without supervision, characterizing autonomous simulation [27]. In the remaining studies, no information was provided about the facilitator's role during the simulation [24,26].

Formal validation of scenario design was not reported in any study. One study used a validated clinical algorithm to structure the expected sequence of actions [27], while others reported that scenarios were based on clinical practice situations and reviewed by faculty members or experts [25,26].

Curricular integration was explicitly described only by Vogel et al [24], who used AR simulation as a complement to theoretical and practical obstetric teaching. Other studies did not specify whether the interventions were embedded in formal curricula. Across studies, immersive simulation was combined with additional teaching strategies, including preparatory reading, digital guide, lectures, mannequin-based teaching, clinical skills training, team-based role-play, and digital learning materials [24-27].

Instruments and Assessment

The included studies used different assessment instruments, which were distributed across the domains of knowledge, skills, and attitudes, in addition to addressing aspects related to the learning experience.

Theoretical knowledge was assessed using instruments constructed by the authors themselves based on the objectives of the intervention [24] or developed within the context of international educational programs [27].

Clinical skills were evaluated through checklists applied during the simulation [25,26], in Objective Structured Clinical Examination (OSCE) stations [27], and through online questionnaires of self-perceived practical performance [24].

Attitude was assessed in 2 studies, through validated self-administered scales that measured self-confidence [25] and self-directed learning ability [26].

Learning experiences and perceptions of the simulated environment were addressed differently across studies. Only Öner and Turfan [25] used validated scales to measure satisfaction, immersion perception, scenario design, and pedagogical practices. In the others, nonvalidated questionnaires were applied to assess aspects such as satisfaction [26], usability, realism, and clinical applicability [27].

Outcomes of the Educational Interventions

The included studies reported outcomes related to knowledge, practical skills, attitudes, and learning experience. Overall, findings suggested positive effects of VR- and AR-based interventions, particularly for practical skills, self-confidence, satisfaction, and perceived learning. However, the heterogeneity of outcome measures, assessment instruments, and follow-up periods limited direct comparison across studies.

Knowledge outcomes were assessed in 2 studies [24,27], with mixed findings. Vogel et al [24] reported significant improvements in perceived knowledge after AR simulation across all simulated clinical scenarios. In contrast, Umoren et al [27] found no statistically significant differences between groups in theoretical knowledge following an in-person course, although participants had only been exposed to the VR application for technical familiarization at that stage.

Practical skills were assessed in all 4 studies. Three studies reported significant improvements or higher performance associated with immersive simulation [24-26]. The strongest differences were observed when VR was combined with CBL, particularly for team-based skills [26], and when VR was compared with low-fidelity simulation for newborn care training [25]. In contrast, Umoren et al [27] did not identify statistically significant differences between groups in immediate or long-term skills performance, although the VR group showed a trend toward better retention at follow-up. Detailed findings for practical skills are presented in Table 3. As Vogel et al [24] did not include a control group, their results were not included in this analysis.

Attitudinal outcomes were assessed in 3 studies. Improvements were reported in self-confidence after AR simulation [24] and VR simulation [25], while Zhao et al [26] found gains in self-directed learning, including self-management, information processing, and collaboration, compared with traditional lecture-based teaching.

Learning experience was generally evaluated positively across studies. Participants reported favorable perceptions of satisfaction, usability, realism, clinical usefulness, immersion, and educational value [24-27]. However, validated instruments were used inconsistently, limiting comparison across interventions. Reported implementation challenges included mobile device compatibility issues, AR marker detection failures, dependence on project-provided smartphones, low adherence to recommended practice, and symptoms such as dizziness, nausea, or mild cybersickness [24-27].

[c]OSCE: Objective Structured Clinical Examination.

[d]Pass rate (%). Percentages are reported as presented in the original studies.

[e]Effect size not reported in the original study.

[f]BMV: bag-and-mask ventilation.

Methodological Quality and Risk of Bias

Overall, the included studies presented low to moderate risk of bias, with methodological limitations mainly related to blinding, allocation concealment, outcome measurement, and control of confounding factors. These limitations are common in educational intervention research but should be considered when interpreting the findings.

The 2 randomized controlled trials reported randomization, baseline comparability between groups, appropriate outcome assessment methods, and adequate statistical analyses [25,27]. However, allocation concealment was not described, and blinding of participants, intervention providers, or outcome assessors was not implemented. In addition, Öner and Turfan [25] did not report an intention-to-treat analysis, and the use of self-assessment measures may have increased the risk of measurement bias.

The 2 quasi-experimental studies reported a clear temporal relationship between intervention and outcomes, complete follow-up, and appropriate statistical analysis [24,26]. However, only Zhao et al [26] included a control group and reported baseline similarity between groups. In both quasi-experimental studies, limited information was provided on strategies to standardize data collection or ensure consistency among assessors. Vogel et al [24], which used a single-group pre-post design, did not report procedures to control for potential cointerventions.

MERSQI scores ranged from 10.0 to 14.5, with a mean score of 12.9 (SD 2.0), indicating moderate methodological quality overall. Higher scores were associated with stronger study designs, objective outcome measures, and appropriate statistical analyses. Lower scores mainly reflected limited evidence of instrument validity, single-institution sampling in most studies, and the absence of higher-level educational outcomes. Detailed MERSQI scores are presented in Multimedia Appendix 2.

XSL•FO
RenderX

Given the small number of included studies and the heterogeneity in interventions, outcome domains, assessment instruments, and timing of evaluation, a formal GRADE (Grading of Recommendations Assessment, Development, and Evaluation) assessment was not conducted. Instead, the overall confidence in the evidence base was assessed narratively, considering study design, risk of bias (JBI), methodological quality (MERSQI), consistency and directness of findings, and the use of validated outcome measures. Reporting bias could not be formally assessed using statistical methods, such as funnel plots, due to the limited number of studies and the absence of pooled effect estimates.

Discussion

Overview

This systematic review examined how VR and AR have been integrated into obstetric nursing and midwifery education, with particular attention to theoretical grounding, instructional design, technological characteristics, and educational outcomes. The findings indicate that immersive technologies have been used mainly to support the development of technical competencies in obstetric and neonatal care, particularly in childbirth procedures, emergency scenarios, immediate newborn care, and neonatal resuscitation. However, the evidence base remains limited, consisting of only 4 heterogeneous studies, and the pedagogical and technological reporting of the interventions was often incomplete.

In general, the included studies suggest that VR- and AR-based interventions may improve immediate learning outcomes, particularly practical skills, self-confidence, satisfaction, and perceived learning. However, the incorporation of theoretical frameworks and instructional design was limited, and these findings should therefore be interpreted with caution.

Theoretical and Pedagogical Grounding

A central finding of this review was the limited explicit use of theoretical or pedagogical frameworks.

Only one study referred to the Jeffries Simulation Theory [28], and another integrated CBL as a pedagogical strategy [26]. The remaining studies did not clearly describe the theoretical assumptions guiding the design, implementation, or evaluation of the XR-based interventions. This is relevant because, in technology-enhanced simulation-based learning, conceptual clarity is essential to strengthen pedagogical coherence, methodological rigor, and reproducibility [5]. Theories provide the conceptual foundation for selecting instructional strategies and organizing learning experiences according to learners' prior knowledge, motivation, and educational needs [30,31], while the instructional models translate these theoretical foundations into practical teaching strategies.

This finding is consistent with previous reviews showing that the absence or superficial use of theoretical frameworks remains a recurrent limitation in simulation and immersive technology research in nursing education [9,10,32]. Although constructivist and experiential approaches, such as Kolb Experiential Learning Theory [33], are frequently cited in VR simulation and technology-mediated nursing education [10,34], the studies included in this review rarely made explicit how learning theory informed scenario design, facilitation, feedback, or assessment. As a result, the interventions often appeared primarily technology, or procedure, driven rather than theory-informed.

Recent models specific to immersive learning, including the Cognitive Affective Model of Immersive Learning (CAMIL) [35], the Immersive Virtual Reality Pedagogical Model (iVRPM) [36], and embodied approaches to immersive extended reality [37], are useful for interpreting this gap. These models highlight constructs such as presence, agency, interactivity, feedback, embodiment, and cognitive engagement as mechanisms through which XR may support learning. However, in the included studies, these mechanisms were seldom assessed or clearly operationalized. For example, presence was measured in only one study [25], while constructs such as agency, cognitive load, usability, embodiment, and learner control were either not evaluated or insufficiently reported. Therefore, although these models offer relevant conceptual guidance, their application in obstetric nursing and midwifery XR education remains limited and requires further empirical validation.

The review also identified a lack of nursing or midwifery theoretical models oriented toward clinical practice. None of the included studies incorporated frameworks addressing comprehensive, relational, woman- and family-centered care, despite the relevance of these dimensions to nurse-midwives' professional practice [38]. This omission may contribute to a predominantly technicist approach to XR-based education, focused mainly on procedural performance and emergency management, while giving less attention to communication, emotional support, shared decision-making, and professional values [39]. Continuous exposure to the theoretical foundations of the profession can help students recognize how these principles apply in real care contexts [40] and may support patient-centered decision-making and therapeutic interventions [41,42]. Nevertheless, future XR interventions in obstetric nursing and midwifery should more explicitly integrate disciplinary theories to ensure that immersive simulation supports not only technical competence but also holistic and person-centered care.

Instructional Design Models

Instructional design was another area with limited explicit reporting across the included studies. Although some interventions incorporated pedagogical strategies such as CBL, repeated practice, preparatory activities, and feedback, none clearly described the instructional principles or models guiding the organization, sequencing, or progression of the learning experience. This limits the interpretation of how VR or AR was integrated into the educational process and reduces the replicability of the interventions in other contexts [30].

This gap is relevant because immersive technologies should not function as isolated or decontextualized learning activities, but as components of a broader instructional plan aligned with learning objectives, learner characteristics, and expected outcomes [30,43] as their effectiveness depends on the quality of instructional design [44]. Instructional design models such as Gagné's 9 events of instruction [45], Analysis, Design, Development, Implementation, and Evaluation (ADDIE)[46],

XSL•FO
RenderX

and Four-Component Instructional Design (4C/ID) [47] have been successfully applied in health and nursing education, including in obstetric emergency training and complex educational programs [48-50]. However, none of the studies included in this review explicitly adopted these or other structured instructional design models.

Although 2 studies [24,25] reported using the International Nursing Association for Clinical Simulation and Learning (INACSL) Healthcare Simulation Standards of Best Practice [29], their operationalization was only partially described, with key components such as learning objectives, briefing, facilitation, scenario design, feedback, and debriefing inconsistently reported.

The mapping of the interventions to Bloom's Taxonomy [18] showed that most studies addressed cognitive and psychomotor domains, mainly through the application of knowledge and performance of clinical procedures. However, the taxonomy was not explicitly used in instructional planning. This limits understanding of whether the degree of immersiveness and interactivity was intentionally aligned with different levels of cognitive complexity, as recommended in technology-mediated learning environments [36,51]. Similarly, although the Kirkpatrick model [19] was useful for interpreting evaluation levels, it was not explicitly adopted by the primary studies. All studies assessed learning outcomes, and some assessed satisfaction or perceptions, but none evaluated transfer to clinical practice or organizational or patient-related outcomes, reflecting a recurrent limitation in health professions education research [52].

The limited description of preparatory activities, briefing, and debriefing is particularly important in XR-based simulation. From the perspective of Cognitive Load Theory [53], these components may help manage the cognitive demands of immersive environments by preparing learners for the task, reducing unnecessary ambiguity, and supporting reflection after the experience. All studies described some form of preparation, such as theoretical classes, preparatory reading, technical instructions, practical training, or mannequin-based activities [24,26]. These strategies may have helped students build prior knowledge and reduce task complexity [31,54]. However, structured pedagogical briefing was rarely reported; most studies focused on technical familiarization with VR or AR devices rather than on broader briefing elements such as learning objectives, roles, expectations, psychological safety, confidentiality, and the fiction contract [10,55].

Debriefing was also insufficiently described. Only one study reported a structured debriefing process supported by a theoretical framework [25]. Another combined automated feedback with facilitator-guided discussion, suggesting a potentially useful hybrid approach [26]. Evidence indicates that debriefing and immediate feedback can strengthen clinical competence in VR simulation by supporting reflection, repetition, and individualized learning [56]. Automated feedback may therefore have pedagogical value when it is intentionally designed and aligned with learning objectives, but it should not be considered a substitute for facilitator-led reflective debriefing [57].

Pedagogical Implications of Immersiveness and Interactivity in Learning

The reviewed interventions used immersive and interactive technologies to support experiential learning in obstetric and neonatal scenarios. VR interventions generally relied on HMDs to create 3D environments, while the AR intervention used smartphone-based interaction. These features may enhance presence, realism, active participation, and knowledge retention when they are pedagogically aligned with the learning objectives [35,36,58].

However, the included studies provided limited information on how the level and type of immersion were selected or justified. In simulation-based education, immersion should not be understood only as physical or technological realism. Rather, different dimensions of fidelity may support different learning goals. Physical fidelity refers to the extent to which the simulation resembles the real clinical environment in sensory or material terms, whereas functional fidelity concerns the extent to which the simulation reproduces the relevant clinical tasks, decision pathways, and responses. Psychological fidelity refers to the extent to which the scenario engages learners cognitively and emotionally, encouraging them to think and act as they would in clinical practice. In this sense, high physical realism may be useful for spatial orientation, procedural familiarization, and anatomical understanding, while functional and psychological fidelity may be more important for clinical reasoning, diagnostic decision-making, communication, and prioritization in complex obstetric situations [59-61].

This distinction is particularly relevant for XR-based obstetric education. For lower-level cognitive objectives, such as remembering or understanding, highly immersive or highly interactive environments may not be necessary. Greater interactivity and psychological engagement may be more appropriate when learners are expected to apply knowledge, analyze clinical cues, make decisions, or coordinate care in emergency scenarios [38]. Thus, the educational value of VR and AR depends less on maximizing realism in all dimensions and more on aligning the type of fidelity with the intended competencies.

The findings also suggest that immersive design should be considered in relation to cognitive load. High levels of sensory stimulation, realism, or interaction may support engagement, but they may also increase extraneous load if learners are insufficiently prepared or if interface complexity distracts from the clinical task [11]. Although some studies described technical familiarization or preparatory activities, none explicitly reported how physical, functional, or psychological fidelity, interface design, or task complexity were adjusted to learner proficiency or cognitive demands.

Among the studies analyzed, only Öner and Turfan [25] assessed the sense of presence, reporting high perceived immersion and a positive relationship with students' performance and satisfaction. Zhao et al [26] also reported positive perceptions related to satisfaction and self-confidence. However, Umoren et al [27] found low adherence over time despite good usability, suggesting that ease of use and physical immersion alone may not ensure sustained engagement or motivation [58].

XSL•FO
RenderX

Although all studies described first-person interaction and the performance of clinical actions in 3D environments, none detailed the technical characteristics of the systems used, such as visual fidelity, navigation freedom, or decision-making mechanisms. Conversely, research indicates that these features of VR and AR are particularly effective for teaching complex anatomical and spatial content, with positive results also observed in obstetrics, especially due to the ability to visualize the dynamic relationship between the fetus and the maternal pelvis [1,3,8]. In addition, the incorporation of haptic resources and tactile, auditory, or visual feedback can enhance the sense of realism and encourage learners to reflect on their actions, thereby fostering the development of clinical reasoning. However, when poorly calibrated, these additional stimuli may cause distraction or sensory overload [11].

The technical diversity of the included interventions also indicates that the findings should not be interpreted as reflecting a homogeneous "XR effect." HMD-based VR, smartphone-based HMD VR, and smartphone-based AR differ in the type and degree of immersion they provide, as well as in their potential to support presence, spatial understanding, embodied interaction, and learner control. Therefore, as immersive technologies continue to expand in health professions education, there is a growing need to better understand the mechanisms through which learning occurs in these environments. Beyond the assessment of learning outcomes, future research should incorporate key constructs such as presence, agency, and cognitive load, assessed using validated instruments (eg, the Multidimensional Cognitive Load Scale for Virtual Environments [62], the Presence Questionnaire [63], and NASA-TLX [64]), as well as usability measures (eg, virtual reality system usability questionnaire [65]), to provide a more comprehensive understanding of XR-based learning processes.

Educational Effects of VR- and AR-Based Interventions

The included studies reported generally favorable educational outcomes for VR- and AR-based interventions, particularly in relation to practical skills, self-confidence, satisfaction, and perceived learning. However, these findings should be interpreted cautiously because the evidence base was small, heterogeneous, and mainly limited to short-term educational outcomes.

Assessment strategies varied considerably across studies, with a predominance of measures related to technical skills, learning experience, and perceived self-confidence. Most studies assessed outcomes immediately after the intervention, limiting conclusions about retention and transfer to clinical practice. Only Umoren et al [27] included follow-up assessment, suggesting a possible benefit of VR for the retention of psychomotor competencies. However, the absence of longitudinal assessment in the remaining studies prevents broader conclusions about the sustainability of learning effects.

The reviewed studies were concentrated at Kirkpatrick level 2, as they assessed learning outcomes such as knowledge, skills, and attitudes. Some studies also addressed level 1 outcomes, including satisfaction and perceptions of the learning experience. However, none evaluated level 3 (behavioral change in clinical practice) or level 4 outcomes (organizational, clinical, or patient-level impact) [19]. This distinction is important because improvements observed in simulated learning environments should not be interpreted as direct evidence of improved clinical performance or patient outcomes. Capturing higher-level Kirkpatrick outcomes is particularly challenging in obstetric emergency education. Events such as neonatal resuscitation, dystocia, umbilical cord prolapse, or emergency cesarean preparation may be high-risk but relatively infrequent, making it difficult to observe sufficient real-world cases after training. This limitation is consistent with previous reviews on virtual reality [66] and reflects methodological challenges inherent to clinical training, where assessing behavioral change in real practice and linking training to patient outcomes require longitudinal follow-up and are influenced by multiple confounding factors [52]. This may result in imprecise evidence, as observed in reviews of simulation in obstetric emergencies [67], reinforcing the need for caution when interpreting and measuring these outcomes.

Most interventions focused primarily on psychomotor skills and basic cognitive outcomes, especially the understanding and application of technical procedures. This focus is consistent with previous evidence suggesting that immersive technologies may support cognitive, psychomotor, and affective outcomes among nursing students and nurses [2,68], with promising applications in obstetric education [69]. However, higher-order cognitive processes were less consistently addressed. Zhao et al [26] was the only study that clearly stimulated clinical reasoning and decision-making through a CBL approach, integrating case analysis, diagnosis formulation, and procedural execution. This finding aligns with evidence associating VR with critical thinking and cognitive engagement among nursing students when it is embedded in intentional instructional design [12,70].

Despite the promising results in the cognitive and psychomotor domains, Zhao et al [26] was the sole study to address aspects of communication and teamwork, which were evaluated in the context of collaborative clinical case resolution. Recent evidence broadens this discussion by demonstrating that the use of immersive virtual environments can promote significant gains in communication, leadership, situational awareness, teamwork, and decision-making [71], particularly when there is a high degree of realism and interactivity [5,71]. These are fundamental competencies for safe clinical performance in obstetric contexts. Nevertheless, the literature indicates that the development and structured assessment of these competencies in VR and AR–based programs remain incipient, representing an important challenge for future research in obstetric and nursing education [32].

The included studies predominantly focus on procedural skills, with limited attention to the relational dimensions of care, revealing an important imbalance in midwifery training, which requires the integration of clinical, emotional, and interpersonal components [38].

XSL•FO
RenderX

Implications and Recommendations for Educational Practice

The integration of simulation mediated by VR and AR in obstetric education requires coherence among theoretical foundations, instructional design, technological features, and expected outcomes. Immersive technologies should be used as pedagogical tools within a structured educational program, rather than as isolated technological experiences. This recommendation is consistent with the recent Utstein-style consensus agenda for XR in health care simulation, which emphasizes evidence-informed adoption, faculty readiness, institutional investment, data-driven evaluation, and sustainable integration of XR technologies in health professions education [72].

Considering the context of obstetric nursing and midwifery education, nursing theories can guide the principles of comprehensive and person-centered care, reinforcing the ethical and disciplinary commitments of the nursing and midwifery professions. These values should permeate the construction and implementation of simulation scenarios, ensuring that students develop clinical judgment, ethical awareness, and decision-making grounded in evidence and in the needs expressed by women and their families.

In instructional planning, it is recommended that VR and AR be integrated into the curriculum as part of a continuum connecting theory, simulated practice, and clinical practice. To achieve this, it is suggested to use instructional design models that intentionally and systematically integrate different teaching strategies, including immersive technologies, grounded in the articulation between pedagogical theory and the expected learning outcomes.

The level of immersiveness and interactivity should be adjusted according to the cognitive levels involved and the learners' proficiency, balancing realism and cognitive load. Less immersive environments are indicated when the focus is on understanding concepts and initial procedural practice, whereas highly immersive simulations are recommended for learning objectives involving clinical reasoning and decision-making in complex obstetric contexts. Furthermore, obstetric education can leverage the potential of VR and AR to represent dynamic anatomical and physiological structures, such as the relationship between the fetus and the maternal pelvis during labor, thereby enhancing spatial understanding and clinical reasoning, provided that the simulation design avoids sensory distractions and maintains intentionality in all elements of the scenario.

Clinical simulation mediated by immersive technologies should follow international guidelines for best practices in clinical simulation, ensuring both pedagogical and ethical quality. Preliminary preparation is recommended to reduce intrinsic cognitive load through familiarization with the technology and the learning content. It is important to consider briefing as an essential stage for reducing extraneous cognitive load by aligning objectives and expectations, while facilitation should monitor and adjust cognitive load during the simulation, providing support compatible with the learner's proficiency level and encouraging autonomy.

Automated sensory feedback from virtual platforms can be useful for validating actions or signaling the need for adjustments in clinical reasoning, and when complemented by facilitator-mediated feedback, it promotes reflective learning and deeper understanding. During debriefing, conducted in a structured manner, it is important to include reflection on technical and behavioral dimensions related to woman- and family-centered care.

The evaluation of simulations mediated by VR or AR should encompass multiple dimensions and outcome levels, in alignment with the New World Kirkpatrick Model [19] and the cognitive, psychomotor, and affective domains. Evaluation should occur at different points in time, monitoring the retention and transfer of skills to obstetric care settings, and the results should provide feedback for the continuous improvement of the design, facilitation, and curricular integration of immersive technologies.

Limitations of the Review Process

In addition to the limitations of the included studies, some limitations of the review process should be acknowledged. The small number of included studies and their substantial heterogeneity limited direct comparisons across interventions. Although the included studies reported generally favorable educational outcomes, the evidence reflects considerable variation in technologies, pedagogical approaches, outcome measures, and assessment time points.

Furthermore, the synthesis was constrained by the information reported in the primary studies, precluding formal assessment of reporting bias and certainty of evidence. Consequently, the overall confidence in the evidence is limited. Most outcomes were restricted to satisfaction, perceived learning, knowledge, or skills, with no evidence on transfer to clinical practice or impact on organizational or patient outcomes.

Accordingly, these findings should be interpreted as preliminary, despite their potential implications for midwifery and obstetrics education.

Conclusion

Evidence suggests that VR and AR may support learning in obstetric nursing and midwifery education, particularly in relation to practical skills, self-confidence, satisfaction, and perceived learning. However, the overall certainty of the evidence remains limited because of the small number of heterogeneous studies.

Stronger integration of learning theories, instructional design models, simulation best-practice standards, and validated assessment strategies is needed. Future XR-based interventions should be pedagogically intentional, transparently reported, and aligned not only with technical competence but also with the relational, ethical, and woman-centered nature of obstetric and midwifery care.

Correction of: https://nursing.jmir.org/2026/1/e77051

(JMIR Nursing 2026;9:e98552) doi:10.2196/98552

In "Perceptions and Intentions of Nursing Students Regarding Digital Health: Cross-Sectional Study" [1], the authors made one correction.

The file originally published as Multimedia Appendix 2 has been replaced with the correct questionnaire corresponding to this study, which is attached here as Multimedia Appendix 1.

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Multimedia Appendix 1
Study questionnaire assessing nursing students' perceptions, experiences, and attitudes toward digital health technologies (revised Multimedia Appendix 2).

Abstract

Background: Effective interprofessional collaboration (IPC) in patient discharge planning is essential for ensuring continuity of care, improving patient outcomes, and strengthening coordination among health care professionals. Nurses often serve as primary coordinators due to their continuous engagement in patient care. However, the implementation of IPC continues to face barriers at the individual, team, and organizational levels. Many hospitals have adopted digital tools, such as integrated patient progress notes (IPPNs), to facilitate information sharing. Nevertheless, the use of these tools to support IPC remains suboptimal and has been insufficiently explored, particularly within the Indonesian digital health context.

Objective: This study aimed to explore how IPPNs support IPC during patient discharge planning, particularly from the nursing perspective.

Methods: A qualitative phenomenological study was conducted at a hospital in Bukittinggi, West Sumatra. Data were collected through in-depth interviews and a focus group discussion involving 9 purposively selected health care professionals. Thematic analysis was used to identify key patterns related to IPC practices and communication dynamics involving the use of IPPNs.

Results: The findings revealed 3 main themes: (1) individual understanding and motivation in IPC, encompassing motivation, role expectations, personality style, and professional strengths; (2) team dynamics, including leadership, management, communication, and social support; and (3) organizational support for IPC, comprising collaborative culture, institutional goals, organizational structures, and the organizational environment. Participants perceived IPC as essential yet inefficiently utilized for coordinating patient care across disciplines, with limitations in standardization, accessibility, and clarity of digital documentation hindering effective collaboration.

Conclusions: This study demonstrated that IPC practices were shaped by individual, team, and organizational factors, with digital communication holding a potentially transformative role in facilitating collaboration. These findings contribute to existing knowledge by highlighting context-specific challenges in Indonesian digital health settings, including digital literacy, system usability, and institutional support, which influence IPC and discharge planning outcomes. Integrating digital optimization within IPC frameworks may represent a valuable strategy for advancing digital health practices.

(JMIR Nursing 2026;9:e81961) doi:10.2196/81961

KEYWORDS

digital health; digital communication; discharge planning; electronic health records; health information systems; interprofessional collaboration; integrated patient progress notes; qualitative study

Introduction

Patient discharge from hospital care represents a critical stage in the care continuum, particularly for individuals with chronic or complex conditions [1]. Effective discharge planning requires interprofessional collaboration (IPC) to ensure continuity of care and minimize adverse health outcomes [2]. Nurses play a central role as patient and family educators and function as key coordinators of interprofessional communication. However, IPC remains suboptimal in many health care systems, particularly in low- and middle-income countries (LMICs), contributing to prolonged hospital stays, medication errors, fragmented care, and reduced patient satisfaction [1,3].

Technological innovations have been identified as potential strategies for enhancing IPC. Web-based platforms, such as *Discharge Today*, have demonstrated improvements in team

XSL•FO
RenderX

coordination without increasing workload, with most users perceiving the information as accurate and useful [3]. In situations with limited face-to-face interaction, such as shift handovers, these tools support continuity of information exchange among team members [4]. Virtual simulation–based interprofessional education (IPE) has also been shown to strengthen collaborative competencies among health care professionals, particularly nursing students [5]. However, the successful implementation of such interventions is highly dependent on health care professionals' digital readiness, motivation, and technological competence.

Barriers to effective IPC persist at both institutional and individual levels. Organizational constraints, including weak leadership and inadequate managerial support, hinder technology-enabled collaboration and contribute to poor communication and reduced team performance [6,7]. At the individual level, resistance to change, heavy workload, limited digital literacy, and unclear professional roles impede collaboration, particularly during discharge transitions [2,6].

Digital documentation tools, including electronic health records, shared care plans, and standardized discharge forms, are designed to support IPC by improving clarity and consistency of clinical information [3]. However, practical challenges, including documentation fatigue, limited training, and system incompatibility, often limit their optimal use in clinical practice [4].

In Indonesia, hospitals have adopted an integrated patient progress notes (IPPNs), locally known as *Catatan Perkembangan Pasien Terpadu*, as part of the national electronic health records system to support multidisciplinary documentation [8]. Although nurses are required to routinely document patient progress using this system, studies have reported implementation inconsistencies, including incomplete entries, lack of standardization, and suboptimal use during discharge planning [9], compounded by unclear protocols, administrative workload, and limited digital literacy training [10].

Similar implementation gaps are evident in a type B teaching referral hospital in West Sumatra that has adopted the IPPNs system as part of its digital health strategy. However, despite being policy-mandated, no formal evaluation has examined the use of IPPNs in supporting IPC during discharge planning, particularly from nurses' perspectives. Existing studies have primarily focused on technical or administrative aspects of documentation, with limited examination of IPPNs as a digital collaboration tool within clinical practice.

This hospital was selected as the study site because it functions as a regional referral center and teaching institution that actively implements national digital health integration and manages multidisciplinary, high-complexity cases requiring intensive interprofessional coordination. These characteristics make it representative of mid-level health care facilities transitioning toward integrated digital health systems. Therefore, this study aimed to explore how IPPNs are used as a digital collaboration tool to support IPC during patient discharge planning, with a particular focus on nurses' perspectives and interprofessional practice.

Methods

Study Design

This study used a qualitative phenomenological design to explore health care professionals' experiences of IPC in patient discharge planning supported by digital documentation in a hospital setting. The phenomenological approach was selected because it enables an in-depth exploration of participants' subjective experiences and the meanings they ascribe to the phenomenon under investigation [11-15].

Setting and Samples

This study was conducted between January and February 2025 at a type B teaching referral hospital in West Sumatra, Indonesia. The hospital has implemented IPPNs, locally known as *Catatan Perkembangan Pasien Terpadu*, as part of its digital service standards. The hospital was selected because it involves multiple health care professions in the collaborative process of patient discharge planning.

Participants were recruited using purposive sampling and comprised 9 participants: 3 physicians, 2 nurses, 2 pharmacists, and 2 nutritionists. This interprofessional composition was intended to reflect collaborative dynamics among health care team members. Data saturation was achieved, as no new themes emerged after the eighth interview, and the ninth interview confirmed thematic repetition. In phenomenological studies, data saturation is typically achieved with 6 to 10 participants who have direct experience with the phenomenon under investigation [12,13].

Although the study was nursing-oriented, 2 nurses were included because the primary focus was IPC in discharge planning rather than nursing practice alone. The selected nurses had direct clinical and coordinative experience in the discharge process, providing sufficiently rich insights to represent nursing perspectives. In phenomenological research, depth and richness of meaning are prioritized over sample size, making this sample appropriate for addressing the research objectives [13,14].

Participants were selected based on the following inclusion criteria: (1) Physicians must hold a valid practice license (Surat Izin Praktik, SIP) and a clinical competency certificate (Surat Keterangan Kewenangan Klinik, RKK), have at least 2 years of work experience at the hospital, and consent to participate; (2) Clinical nurses (level III) must possess an SIP and a signed RKK, have at least 2 years of work experience at the hospital, and consent to participate; (3) Pharmacists must hold an SIP and an RKK, have at least 2 years of work experience at the hospital, and consent to participate; and (4) Nutritionists must hold an SIP and an RKK, have at least 2 years of work experience at the hospital, and consent to participate.

All participants were anonymized and assigned codes to ensure confidentiality and protect personal information throughout the research process.

Data Collection Procedures

Data were collected through in-depth interviews and face-to-face focus group discussions (FGDs) conducted at the hospital. The interview guide was developed based on the World Health

XSL•FO
RenderX

Organization (WHO) IPC framework and King's Interpersonal System Theory, focusing on 4 main domains: (1) perceptions of IPC in discharge planning; (2) roles and responsibilities of each professional group within the team; (3) barriers and facilitating factors influencing IPC implementation in the hospital; and (4) utilization of the IPPNs as a digital communication tool for coordination among professionals.

The following are the example interview questions:

1. How do you perceive IPC in the discharge planning process?
2. What challenges have you encountered when using IPPNs to coordinate with other professionals?
3. In your view, what factors could strengthen interprofessional teamwork in this hospital?

Each interview lasted approximately 45 to 60 minutes, was audio-recorded with participants' consent, and was transcribed verbatim.

Following the individual interviews and initial thematic analysis, an FGD was conducted to validate and refine the themes that emerged from the interviews. The FGD served as a member-checking process to confirm the credibility of the findings and to provide cross-professional reflection on shared experiences. Importantly, the FGD was not intended to generate new themes but to enhance trustworthiness through data triangulation and ensure consistency of meaning across professional perspectives.

All participants received a clear explanation of the study objectives and procedures, and informed consent was obtained before data collection.

Data Analysis

Data collection and analysis were conducted in 2 stages. The first stage involved 9 in-depth interviews using a semistructured interview guide consisting of open-ended questions based on the WHO framework for IPC and the core IPC competencies as outlined by the Institute of Medicine in the expert panel report. The information obtained from these face-to-face interviews was recorded with consent and transcribed verbatim. As the interviews and FGD were conducted in Bahasa Indonesia, data analysis was performed in the original language. Quotations included in the manuscript were translated into English carefully to retain conceptual accuracy. Interview data were analyzed thematically following the approaches proposed by Braun and Clarke [12,13], including open coding, theme development, and interpretation. The coding and theme categorization process was supported by NVivo 15 software (Lumivero) to ensure analytic consistency and traceability.

The reporting of this study adhered to the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist to ensure transparency and methodological rigor. The coding process followed the 6 phases of thematic analysis proposed by Braun and Clarke, including data familiarization, generation of initial codes, searching for themes, reviewing, defining, and naming themes. A preliminary codebook was developed inductively from the data, then refined through iterative discussions among the research team to ensure conceptual clarity. Coding discrepancies were resolved through peer debriefing and consensus meetings to achieve analytic consistency.

The second stage of data collection was an FGD conducted only once, including 4 participants selected from the initial participants based on the richness and relevance of the information provided during the previous analysis. FGD data were analyzed using the same thematic method, and the results from both stages were integrated using triangulation.

Potential bias was addressed in the FGD by ensuring equal opportunities for all participants to speak and by avoiding dominant voices that overshadowed others. The discussion was guided neutrally, with questions designed to elicit further reflection rather than primary responses.

Trustworthiness and Rigor

To maintain the trustworthiness and rigor of qualitative data, the strategies outlined by Nowell et al [14,15] were applied as follows: credibility was ensured through data saturation, verbatim transcription, and triangulation of in-depth interviews and FGDs; transferability was supported by a detailed description of the study context, including participants' profiles and data collection procedures; dependability was ensured through detailed documentation of the data collection and analysis processes; and confirmability was established through triangulation and discussions with study team members to ensure consistent and objective interpretations [14,15].

Ethical Considerations

This study underwent ethical review and was approved by DR Drs M Hatta Brain Hospital, Bukittinggi, Indonesia (002555/KEP.RSOMH Bukittinggi/2024). Before data collection, participants were provided with a study information sheet explaining the purpose, benefits, methods, and participant rights. Participation was voluntary, and participants could withdraw at any time without consequences. Written consent was obtained from each participant after they read and understood the information provided. Confidentiality and anonymity were maintained by excluding individual identities from the report. Data were used solely for this study and stored securely in accordance with privacy policies. The research was conducted in accordance with the Helsinki Declaration. Participants did not receive any financial or material compensation for their participation in this study.

Results

Descriptive Results

Before presenting the main findings, an overview of participant characteristics is provided in Table 1, which summarizes the characteristics of 9 participants, all within the productive age range (25 - 64 y) as defined by the WHO. Most participants were female (n=7, 78%) and held a master's degree (n=7, 78%). The majority were married (n=7, 78%) and had more than 10 years of work experience (n=6, 66.7%).

[a]WHO: World Health Organization.

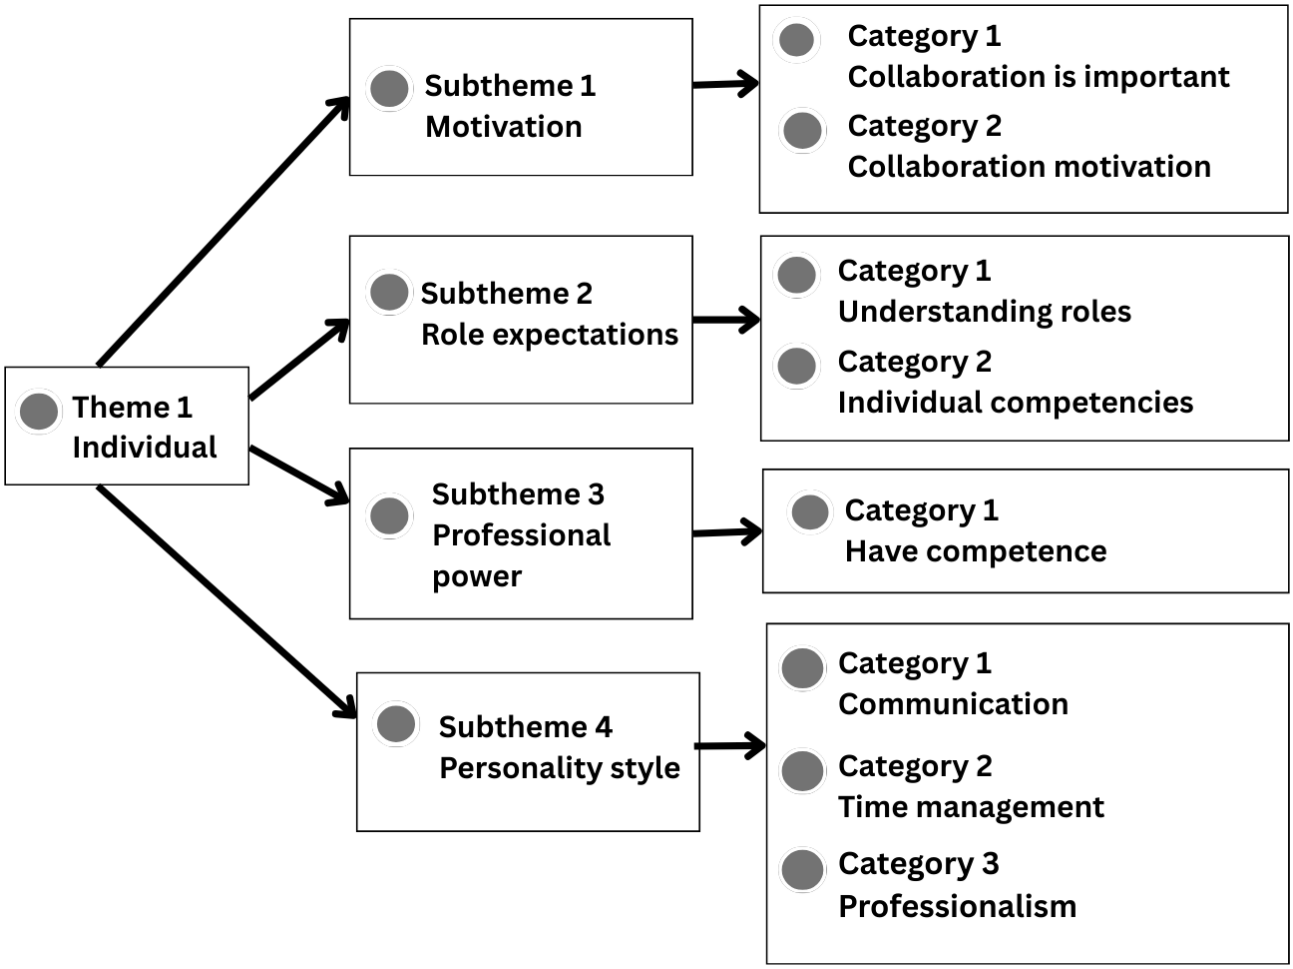
Participants represented 4 professional backgrounds: doctors, nurses, pharmacists, and nutritionists, reflecting multidisciplinary involvement in patient discharge planning.

Health Care Professionals' Experiences in Implementing IPC in Hospital Settings

Overview of Emergent Themes

Three main themes and 12 subthemes emerged from the analysis, describing health care professionals' experiences in implementing IPC during patient discharge planning. The main themes and subthemes are summarized in Table 2.

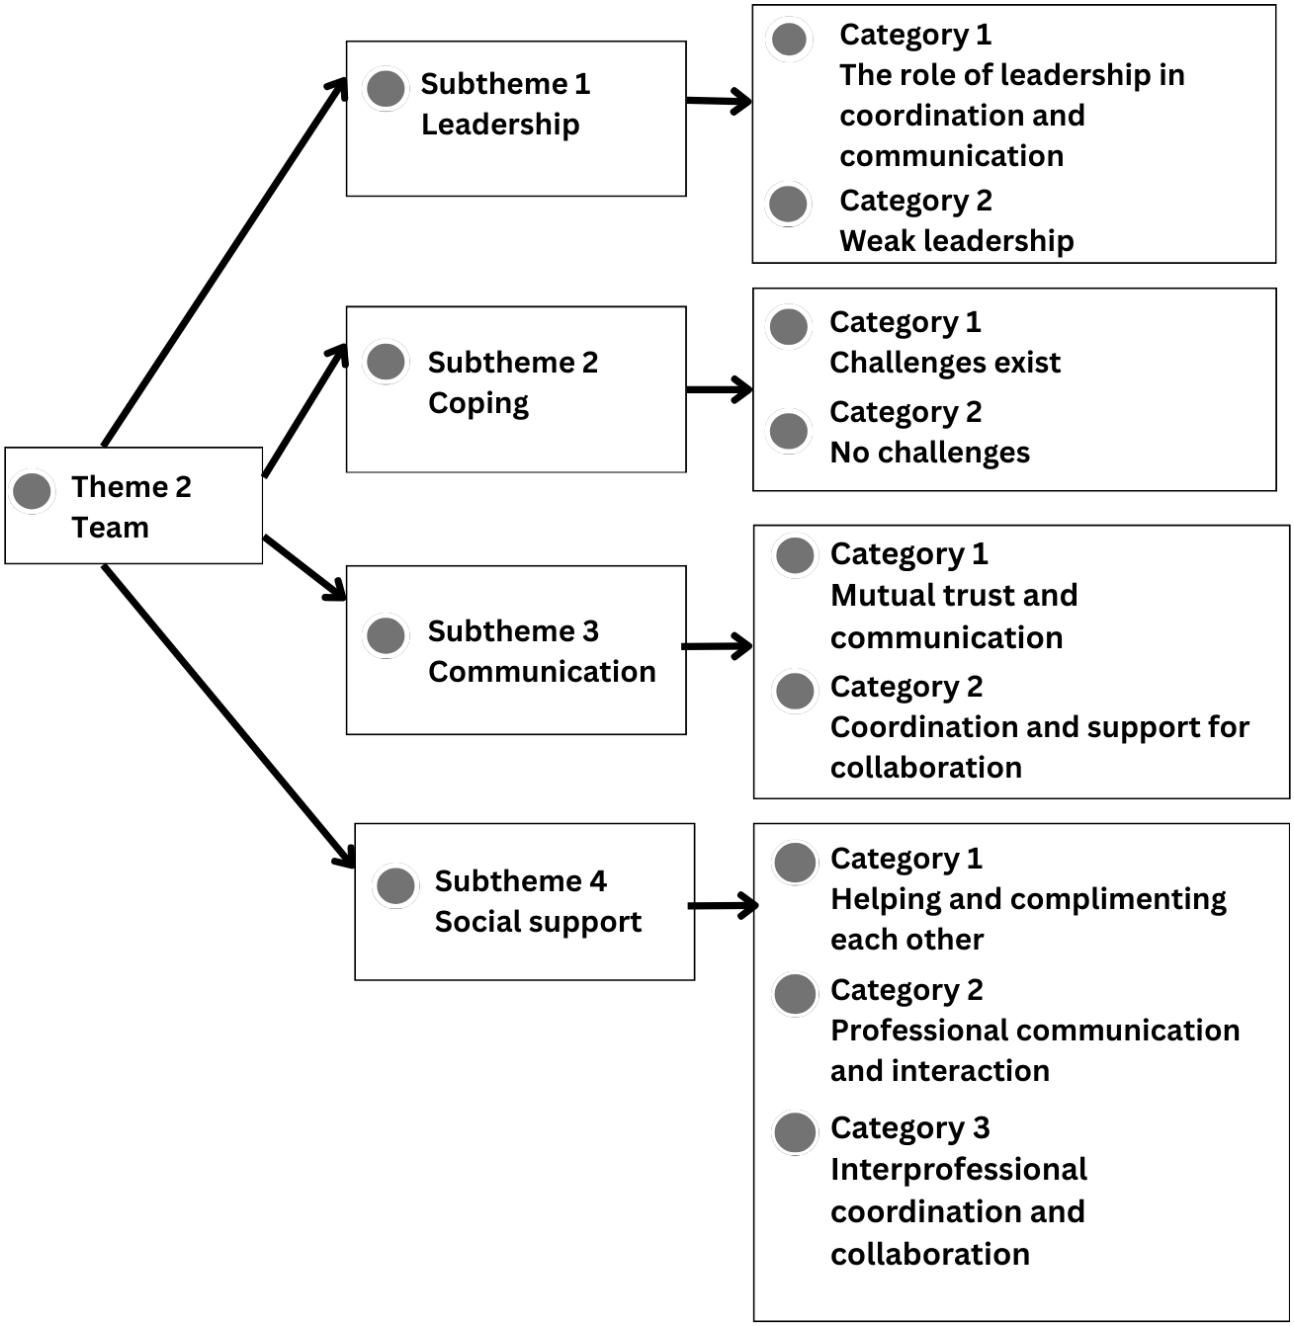
Table . Themes of health professionals' experiences in IPC[a] practice at a type B teaching referral hospital in West Sumatra, Indonesia.



Code	Themes	Subthemes
1	Individual understanding and motivation in IPC	• Motivation • Role expectations • Professional power • Personality style
2	Team interaction dynamics in the discharge planning process	• Group leadership • Coping • Communication • Social support
3	Organizational support for IPC	• Organizational culture • Organizational goals • Organizational domain • The organizational environment

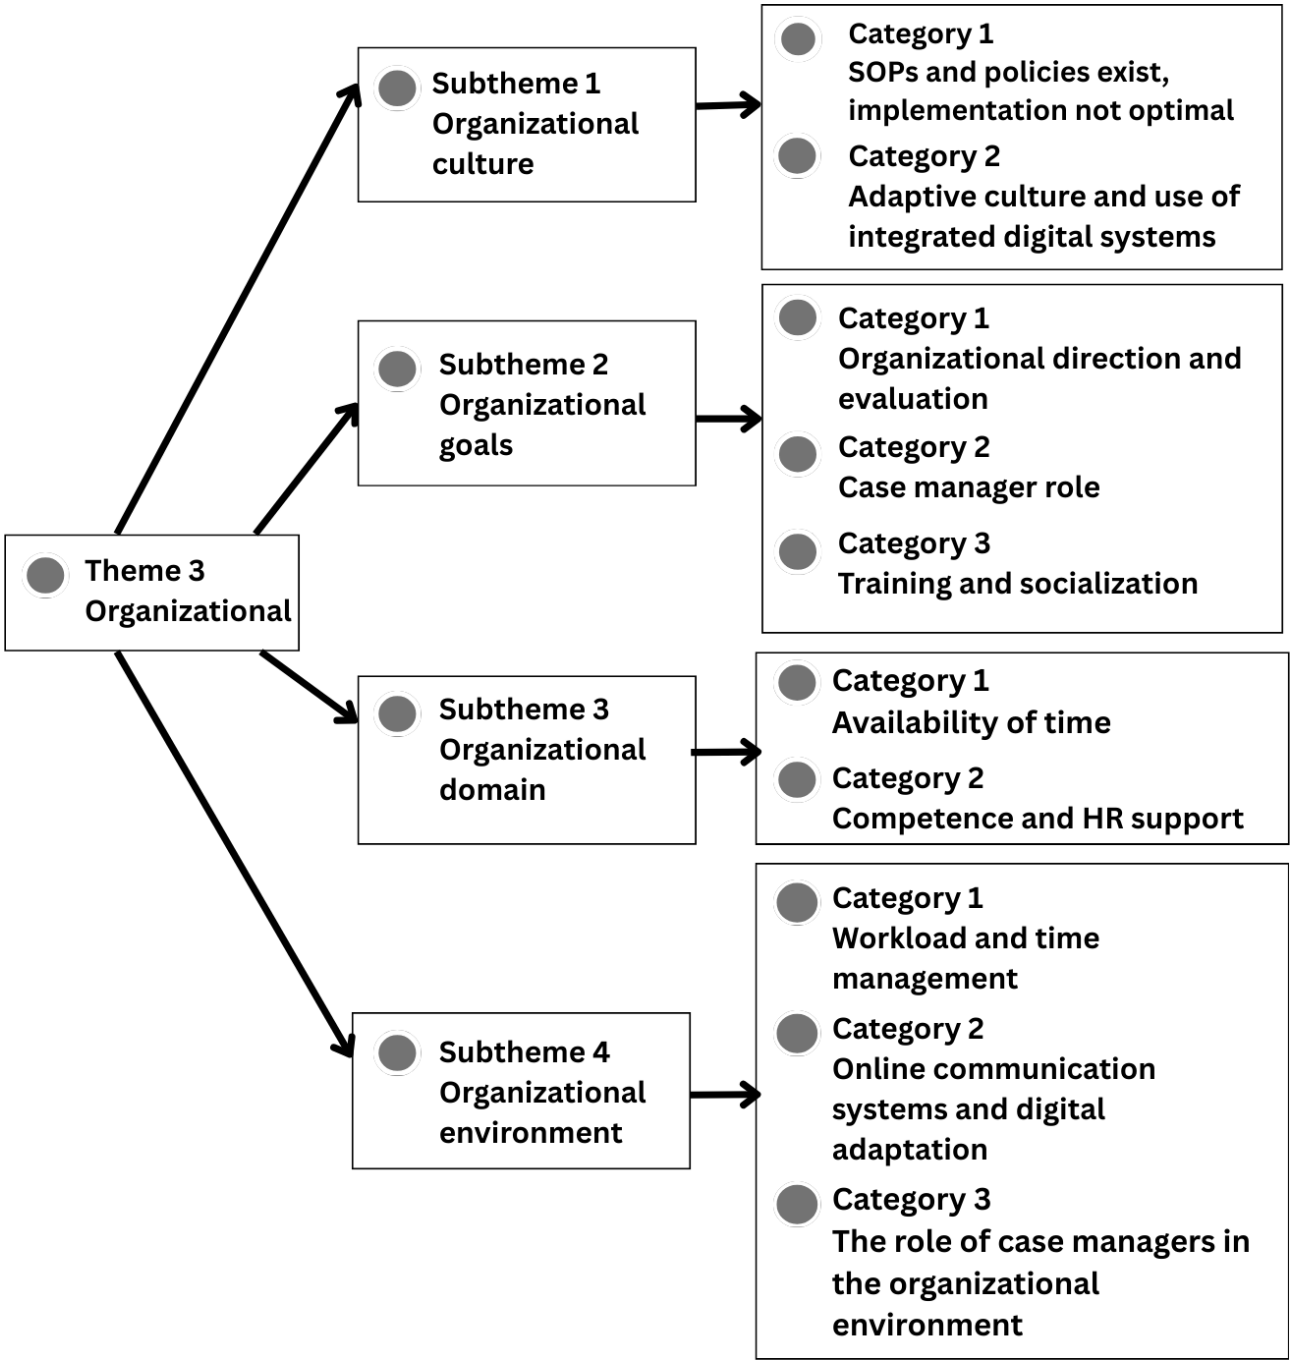
[a]IPC: interprofessional collaboration.

XSL•FO
RenderX



Further details of each theme, including supporting categories and illustrative participant quotations, are presented in Figures 1-3, which were generated using NVivo 15 to visualize the thematic structure, and described in the following sections.

Figure 1. Thematic analysis of theme 1: individual.



XSL•FO
RenderX

Figure 2. Thematic analysis of theme 2: team

XSL•FO
RenderX

Figure 3. Thematic analysis of theme 3: organizational support. HR: human resource; SOP: standard operating procedure.

Theme 1: Individual Understanding and Motivation in IPC

Overview of Theme 1

Qualitative findings suggest that individual factors play a crucial role in the implementation of IPC, particularly in the context of patient discharge planning. This theme comprises 4 subthemes: motivation, role expectations, professional authority, and personality styles, as presented in Figure 1.

Figure 1 illustrates theme 1, "individual factors", which includes 4 subthemes with associated categories: (1) motivation, including the importance of collaboration and collaborative motivation; (2) role expectations, including understanding professional roles and individual competencies; (3) professional authority, including possession of professional competence; and (4) personality style, including communication, time management, and professionalism.

The following sections elaborate on each subtheme and present supporting quotations from the 9 participants.

Subtheme 1: Motivation

Internal motivation emerged as a key driver encouraging nurses to participate actively in collaborative discharge planning. Several participants recognized teamwork as essential to ensuring patient safety and continuity of care.

> *Collaboration is essential, especially in planning patient discharge to avoid mistakes.* [Participant 2]

XSL•FO
RenderX

Nurses also expressed motivation stemming from a desire to provide comprehensive patient education before discharge.

> *I'm driven to collaborate so patients receive the right information before going home.* [Participant 4]

This intrinsic drive was reinforced by shared professional goals and a sense of collective responsibility.

> *I feel more enthusiastic when working with a cross-professional team because we share the same goal—the patient's recovery.* [Participant 5.]

Some participants noted that motivation diminished when their contributions were not equally recognized.

Subtheme 2: Role Expectations

Role clarity influenced participation in discharge planning. Participants emphasized that understanding their professional responsibilities guided their involvement in team discussions.

> *I understand that as a nurse, my responsibility is to educate the patient before discharge.* [Participant 2]

Several participants identified interprofessional communication as part of their professional role.

> *I report the patient's condition to the team before they are discharged.* [Participant 3]

Some nurses reported frustration when their roles were perceived as limited to routine tasks.

> *Sometimes we're seen only as medication providers, but we also educate patients about side effects.* [Participant 9]

This perception gap between professions can act as both a facilitator and a barrier to collaboration, suggesting the need for clearer role delineation and mutual respect in team settings.

Subtheme 3: Professional Power

Professional hierarchy influenced collaborative dynamics. Some nurses expressed confidence in their clinical competence and independence.

> *As a nurse, I feel capable of carrying out discharge planning.* [Participant 3]

Others reported discomfort when expressing opinions in the presence of physicians.

> *Sometimes it's difficult to share opinions because we're seen as subordinates.* [Participant 5]

Training and institutional support were described as contributing to professional confidence.

> *After attending training, I felt more confident managing discharge planning.* [Participant 6]

Conversely, some participants reported that dominant attitudes from certain professionals affected collaboration.

> *Sometimes doctors act like they know everything, which makes it hard for others to express their views.* [Participant 7]

These findings illustrate the dual nature of professional power; it can empower individuals through competence and training or hinder collaboration through entrenched hierarchies.

Subtheme 4: Personality Styles

Interpersonal communication and personal traits influenced teamwork. Participants associated effective collaboration with openness, confidence, and adaptability.

> *I'm used to coordinating and listening to team members' input.*
>
> *[Participant 7]*
>
> *I prefer being open if there's a different view, I take it as constructive feedback.* [Participant 8]

Adaptability was identified as helpful when working with professionals from different disciplines.

> *I'm adaptable and used to working across different professions.* [Participant 9]

Nevertheless, communication gaps were occasionally reported, especially when individuals lacked confidence or were hesitant to speak up. This subtheme underscores that successful IPC depends not only on technical skills but also on interpersonal awareness and flexibility.

Summary of Theme 1

Individual factors influenced participation in IPC during discharge planning. Participants described motivation, role understanding, professional hierarchy, and personal communication styles as shaping their collaborative experiences.

Theme 2: Team Interaction Dynamics in the Discharge Planning Process

Overview of Theme 2

Team interaction dynamics played an important role in the discharge planning process and influenced the implementation of IPC. Participation and coordination among different professional groups were described as central to daily collaborative practice. Participants from various professions, including doctors, nurses, pharmacists, and nutritionists, described diverse interaction patterns that shaped how collaboration was formed, maintained, or hindered during discharge planning. These interaction dynamics encompassed leadership, communication, coordination, and social relationships within the health care team. The identified patterns illustrate how team members worked together to support patient discharge planning in routine practice. The structure of the themes, subthemes, and categories related to team interaction dynamics is presented in Figure 2.

Figure 2 presents Theme 2, "team interaction dynamics", which includes 4 subthemes with associated categories: (1) group leadership, including leadership roles in coordination and communication and weak leadership; (2) coping, including collectively managed challenges and absence of challenges; (3) communication, including mutual trust in team communication and coordination and support for collaboration; and (4) social support, including helping and complementing each other, professional communication and interaction, and interprofessional coordination and collaboration.

XSL•FO
RenderX

Subtheme 1: Leadership

Group leadership influenced the effectiveness of collaboration in discharge planning. Participants described leaders as facilitators who initiated meetings, allocated responsibilities, and guided discussions.

> *Our leader always starts the discharge planning meeting and divides the tasks.* [P1]
>
> *The team leader always guides the discharge planning discussion firmly but openly.* [P2]

Participants described leadership styles characterized by fairness and openness: "Our leader encourages all members to express their opinions" (P3), and "Our leader is wise and willing to listen to all input" (P5). Some participants highlighted emotional control and role modeling by leaders: "Our team leader can maintain harmony, not authoritarianism" (P6), and "Our leader sets an example and supports joint decisions" (P7). Collectively, these narratives underscore leadership that balances authority with inclusivity.

Subtheme 2: Coping/Handling

Participants described both the presence and absence of challenges in IPC. Reported barriers included inconsistent evaluation, limited family engagement, and uneven participation across professions: "The challenges exist, especially because there has been no proper evaluation" (P1); "Coordination is a challenge because not all professions are present during joint visits" (P5). Differences in patient contact among professionals were also noted (P3). Some participants reported minimal challenges due to clear standard operating procedures (SOPs) and defined roles: "There are no challenges because all professions already have clear SOPs" (P6).

Subtheme 3: Communication

Participants described communication as occurring primarily through digital platforms, particularly WhatsApp groups: "Communication is carried out via WA groups" (P2, P7, P8, P9). Verbal discussions and documentation were also used to share patient updates: "We routinely inform each other about patient progress" (P1); "I routinely report patient progress to the team via medical records" (P3). Some participants reported communication challenges among new staff unfamiliar with interprofessional communication practices: "There are minor challenges if there are new employees who do not yet understand the ethics or interprofessional communication" (P6). This indicates the need for structured orientation and communication training within multidisciplinary teams.

Subtheme 4: Social Support

Participants described social support as contributing to team cohesion. They reported mutual trust, respect, and shared responsibility. As participant 1 stated, "I feel supported by other team members, so I am more confident," while participant 3 added, "We respect each other; no one feels more important." Participants also described encouragement and practical support among team members: "My team members always give encouragement and moral support" (P4). Moreover, collective accountability was evident when colleagues substituted for absent members without complaint: "If someone is absent, the team still covers for each other without protesting" (P6); "If someone is absent, the others are ready to change shifts without any problems" (P8).

Summary of Theme 2

Team interaction dynamics influenced IPC during discharge planning. Participants described leadership, communication, coping with challenges, and social support as shaping their collaborative experiences.

Theme 3: Organizational Support for IPC

Overview of Theme 3

Organizational support influenced the implementation of IPC in patient discharge planning. Participants described the role of policies, management, resources, information systems, and work culture in shaping collaborative practice. The structure of the themes, subthemes, and categories for organizational support is presented in Figure 3.

Figure 3 presents Theme 3, "organizational support", consisting of 4 subthemes with associated categories: (1) organizational culture, including existing SOPs and policies with suboptimal implementation and adaptive culture through integrated digital systems; (2) organizational goals, including organizational direction and evaluation, case manager roles, and training and socialization; (3) organizational structure, including availability of time and competence supported by human resources; and (4) organizational environment, including workload coverage, time management, online communication systems, and the role of case managers in supporting IPC.

Subtheme 1: Organizational Culture

Participants reported the presence of SOPs and policies supporting discharge planning. However, limited dissemination and inconsistent implementation were noted.

> *There are SOPs, but access is uneven across units, which can hinder implementation.* [Participant 4]
>
> *[A]lthough collaboration is mandated, the execution remains suboptimal.* [Participant 9]

Some participants described the integration of electronic medical records as supporting collaboration. For example, a participant shared, "The new H-1 discharge policy is linked to electronic medical records, making it more transparent" (Participants 3, 5).

Others noted that implementation at the unit level remained inconsistent: "Although management has established procedures, their execution at the ward level still needs improvement" (Participants 2, 5). A formal structure supporting IPC exists, while cultivating a shared culture that translates into consistent, collaborative behavior in daily clinical work remains a challenge.

Subtheme 2: Organizational Goals

Participants described management support for collaboration through direction, case management, training, and evaluation.

> *There are directions from management, but no overarching policy; however, patient satisfaction remains a central focus.* [Participant 2]

XSL•FO
RenderX

> [The presence of a case manager facilitates cross-professional decisions. Participant 6]
>
> *Periodic training and evaluation are carried out to adjust discharge planning practices.* [Participant 8]

Some participants highlighted the role of digital systems in monitoring collaboration:

> *The iKame system allows us to track multidisciplinary participation.* [Participant 7]

Subtheme 3: Organizational Structure

Participants reported that the availability of discharge planning teams and digital tools supported collaboration. Several participants described sufficient time allocation and improved efficiency through electronic systems. A participant shared, "Time is sufficient as long as roles are clear" (Participant 4), while another added, "Using the electronic system saves time compared to manual charting" (Participant 9). However, human resource limitations were also reported: "Time remains a challenge, but we hope things improve with more staff" (Participants 3, 5).

Facilities and digital access were described as adequate: "computers are available" and "nutrition leaflets and counseling are provided" (Participant 2). Participants also described the hospital's electronic system as structured and role-based: "the IT system supports collaboration" and "access is structured based on role and profession" (Participants 6, 7). In summary, structural elements such as time, facilities, and information systems play a critical role in enabling IPC, although workload distribution and continuity of IPE still require improvement.

Subtheme 4: Organizational Environment

Participants generally perceived the work environment as supportive of collaboration: "The work environment supports collaboration and discussion" (Participant 2). Scheduling and coordination challenges were commonly reported. For example, "lack of adherence to schedules affects plans like physiotherapy" and "conflicting rounds and outpatient duties disrupt communication" (Participant 6).

Some participants suggested integrated scheduling and dedicated interprofessional meetings. "More integrated scheduling and dedicated interprofessional meeting time" (Participant 8). While digital systems were viewed as helpful, some participants preferred direct communication: "IT helps, but direct coordination is still more effective" (Participant 7).

Participants also mentioned the need for regular evaluations: "There should be routine meetings and comprehensive evaluations beyond administrative aspects" (Participant 2). Importantly, individual commitment was stated: "Even with full organizational support, without individual commitment, collaboration won't work" (Participant 9).

Few participants consider IPC to be running optimally. However, the results suggest that organizational improvements, particularly in scheduling, evaluation, and communication, are still needed to sustain collaborative efforts.

Summary of Theme 3

Participants described organizational policies, digital systems, managerial support, training, case managers, and work environment as influencing IPC during discharge planning. They also reported challenges related to policy implementation, scheduling, workload, and communication.

Discussion

Principal Findings

The findings of this study indicate that the success of IPC in patient discharge planning is influenced by 3 main factors: individual factors, team dynamics, and organizational support. Individual factors include motivation, role understanding, professional competence, and personality styles; team dynamics involve leadership, communication, problem-solving abilities, and social support; and organizational support encompasses work culture, service goals, resource availability, and a supportive work environment. These findings underscore that IPC effectiveness depends on the interaction between personal capabilities, effective team processes, and organizational structures.

Before discussing the findings in detail, participant characteristics should be considered, as they influence experiences and perceptions of IPC. All participants (n=9) were within the productive age range of 25 to 64 years, reflecting readiness for IPC and adaptation to digital systems [16]. Most participants were female (78.0%), consistent with the gender distribution in nursing and public health professions, which may influence collaboration dynamics through communicative and empathetic approaches [17]. Most participants held a master's degree (78%), indicating strong academic capacity for understanding IPC concepts and applying digital communication in clinical practice [18,19]. The majority had more than 10 years of work experience (66.7%), contributing to professional maturity and confidence in interprofessional communication [17].

Although only 2 nurses participated, they were selected due to their strategic role as primary coordinators of discharge planning, making them representative of nursing competencies in IPC [16].

Exploring the Professional Experiences of Nursing Professionals

Theme 1: Individual Understanding and Motivation in IPC

Overview of Individual Factors Influencing IPC

The findings demonstrate the critical role of individual factors in IPC implementation during discharge planning. Motivation, role expectations, professional power, and personality traits shaped health care professionals' engagement and readiness. These findings align with international IPC literature, highlighting individual awareness and intrinsic motivation as foundational to effective collaboration.

XSL•FO
RenderX

Motivation

Motivation emerged as a strong internal driver rooted in responsibility for patient safety and care continuity. This aligns with Smith et al [5], who showed that interprofessional simulation strengthened motivation and collaborative readiness, and with Reinders et al [20], who emphasized intrinsic motivation in sustaining discharge coordination. In Indonesian settings, motivation is influenced by workload, resource constraints, and institutional incentives, indicating that it is both intrinsic and contextually shaped [20].

This study further shows that digital platforms such as IPPNs and WhatsApp function as external motivators by facilitating timely information exchange and shared accountability, consistent with global evidence on digital engagement in teamwork [16]. However, infrastructure limitations, technical barriers, and workload concerns remain as challenges [21]. Thus, technology-supported motivation requires organizational training, leadership, and incentives, particularly in LMIC contexts where motivation is more relational than structurally reinforced.

Role Expectations

Clear role understanding enhanced IPC participation, especially in patient education and communication. Conversely, undervalued or ambiguous roles—particularly among nurses—limited engagement. These findings support Tong et al [22], who found that role clarity improves collaboration and mutual respect. In Indonesia, hierarchical traditions and inconsistent policy enforcement continue to constrain role clarity [9,10]. Compared with high-income settings where roles are codified through standardized policies and digital protocols, local adaptation of IPC policies remains essential [16].

Professional Power

Professional hierarchy remained a persistent barrier. Despite clinical competence, some nurses hesitated to voice opinions due to perceived lower status. This mirrors Tan et al [23] and Nie et al [4], who reported that digital tools alone do not flatten hierarchies without inclusive leadership and policy support. In LMIC contexts, unequal authority and weak institutional enforcement limit the transformative impact of digitalization on power relations [4].

Personality Style

Personality traits such as openness, adaptability, and empathy facilitated IPC, consistent with prior studies linking emotional intelligence to effective handoffs and reduced information loss [10,24,25]. In the Indonesian context, strong family involvement added complexity to discharge planning, requiring sensitivity to sociocultural dynamics [26]. Comparable findings in high-income settings also highlight emotional intelligence as a key IPC enabler [27]. These results indicate that IPC effectiveness is shaped not only by systems but also by personal and interpersonal competencies [28].

Critical Reflection

These findings reinforce that IPC is shaped by individual attitudes and professional culture in addition to formal systems. Digital platforms can enhance coordination, but their effectiveness depends on leadership, organizational readiness, and equitable governance. Persistent hierarchies and uneven policy implementation in LMICs underscore the need for capacity building that integrates reflective leadership, interprofessional mentoring, and psychological safety.

Theme 2: Team Dynamics in IPC for Discharge Planning

Overview of Team Interaction Dynamics

Team dynamics revealed the importance of leadership, communication, coping strategies, and social support. While digital platforms facilitated coordination, collaboration quality ultimately depended on leadership consistency, institutional accountability, and cultural readiness.

Group Leadership and Participatory Team Culture

Inclusive leadership fostered trust, shared accountability, and psychological safety, consistent with Bornman and Louw [29] and Keniston et al [30]. Conversely, inconsistent leadership resulted in fragmented communication and unclear roles, reflecting uneven policy implementation and limited leadership development common in LMICs [5].

Coping and Operational Challenges in Coordination

Teams faced logistical challenges such as inconsistent participation and fragmented workflows, echoing findings by Nie et al [4]. Clear SOPs and predefined roles mitigated some challenges, aligning with Buljac-Samardzic et al [31]. Persistent hierarchies and uneven enforcement reflected deeper governance barriers, while family involvement occasionally delayed decision-making when authority was unclear [31].

Communication Infrastructure and Team Transparency

Hybrid communication using WhatsApp, face-to-face meetings, and documentation supported coordination, consistent with Keniston et al [30] and Teuwen et al [32]. However, message overload and unequal participation persisted without shared digital literacy and leadership oversight [21,33-35]. Compared with high-income settings, IPC in Indonesia remains dependent on interpersonal initiative rather than integrated systems [27,34]

Social Support and Emotional Climate

Mutual respect, encouragement, and role flexibility strengthened team resilience, consistent with Cadel et al [34]. These findings align with evidence from high-income contexts showing emotional cohesion as a universal driver of IPC effectiveness [35-42].

Critical Reflection

Digitalization facilitates coordination but does not eliminate hierarchies or policy inconsistencies. Compared with high-income settings, IPC success in Indonesia relies more heavily on interpersonal leadership and local initiative, highlighting the need for aligned policy, leadership development, and collaborative governance.

RenderX

Theme 3: Organizational Support for IPC

Organizational-Level Support for IPC

Organizational support emerged as a prerequisite for sustainable IPC, encompassing culture, goals, structure, and work environment.

Organizational Culture

Although SOPs and policies exist, uneven dissemination and weak supervision limited consistent implementation. Hierarchical norms continued to shape communication despite digital tools. These findings align with Redzewsky et al [40] and Ishii et al [41], emphasizing that policy without localized integration fails to sustain IPC.

Organizational Goals

Leadership support through case managers, training, and evaluation facilitated IPC, although the absence of a comprehensive IPC policy remained a barrier. These findings align with Labrague et al [42], who linked supportive environments to improved safety outcomes.

Organizational Domain

Structural supports such as discharge teams, digital systems, and facilities enhanced IPC efficiency [43-46]. However, workload imbalance and limited IPE persisted [45]. Rawlinson et al [46] emphasized that the success of IPC was strongly influenced by team competencies, including effective communication, clearly defined roles, and consistent organizational support.

Adopting digital systems, such as electronic medical records and the iKame app, streamlines coordination and reduces time burden across professions. However, human resource shortages and compressed work schedules continue to present major barriers. Buljac-Samardzic et al [31] suggested that team structure optimization, including task clarity, adherence to SOPs, and structured time allocation, could alleviate operational barriers to IPC. Digital platforms such as IPPNs and WhatsApp improved responsiveness but remained informally governed, limiting institutional monitoring.

The Organizational Environment

The organizational environment plays a critical role in enabling effective IPC. Factors such as the availability of resources, dedicated time allocation, and structured workflows are essential for fostering a productive collaborative climate. Although digital technologies have been introduced to support interprofessional communication, several structural barriers persist, including noncompliance with schedules, overlapping clinical responsibilities, workload pressure, and a lack of integrated cross-professional scheduling systems. Ginting et al [47] emphasized that while digital tools could facilitate IPC, their effectiveness was limited in the absence of a supportive organizational culture and inclusive leadership.

Beyond systemic factors, individual commitment remains essential to ensure sustainable collaboration. A previous study found that interprofessional trust emerges from the quality and regularity of relationships, individual attitudes, and a supportive organizational culture, and that trust, in turn, enhances communication, coordination, teamwork, and ultimately collaborative outcomes [48]. Similarly, Reeves et al [49] showed that workplaces promoting team reflection and shared evaluation cultivated trust and accountability among professionals.

When compared to high-income settings, where IPC practices are often embedded in digitalized and standardized systems, hospitals in Indonesia face persistent challenges related to uneven digital infrastructure, informal communication channels, and resource limitations. Similar barriers have been observed in other low- and middle-income contexts such as Ethiopia and the Philippines, where digital and managerial gaps hinder consistent IPC outcomes. These contrasts highlight that while policy frameworks may be globally aligned, contextual and resource-based differences shape IPC implementation in diverse health systems [50-54].

These inconsistencies often stem from institutional hierarchies, variable managerial commitment, and uneven digital literacy among professionals, which prevent the full translation of collaborative policies into daily clinical practice [55].

Holistic Interdependence Between IPC and Organizational Support

Cadel et al [34] and Smith et al [56] reported that peer substitution and team solidarity were critical to sustaining IPC, particularly during workforce fluctuations. Interprofessional simulation-based learning was also shown to strengthen team relationships and preparedness for role substitution when necessary. These findings emphasize the importance of organizational support mechanisms, including structured training and adaptive team models that can withstand staffing dynamics.

Link to Regional Evidence

A systematic review found that satisfaction with organizational support and positive attitudes toward IPC were associated with collaboration effectiveness, although not often statistically significant [50]. This highlights the need for systemic approaches to improve working conditions, promote regular training, and implement inclusive interprofessional models in clinical practice.

Critical Reflection

Organizational support for IPC depends on alignment between structure, culture, and leadership. Policies and digital tools alone are insufficient without consistent supervision, organizational learning, and reflective practice. Strong leadership commitment and structured evaluation forums are essential to embed IPC as a sustainable norm.

Strengths and Limitations

This study's strengths include its qualitative phenomenological approach, inclusion of multiple professions, and focus on digital documentation (IPPNs) within a middle-income country context. Methodological rigor was ensured through triangulation and trustworthiness criteria, contributing to theory building in IPC within resource-constrained systems.

Limitations include the single-site setting and small sample size. The study did not fully examine system usability or interoperability, and cultural hierarchies may limit

XSL•FO
RenderX

transferability. Future research should adopt multisite and mixed-method designs to explore system-level and leadership influences on IPC outcomes.

Conclusion

In conclusion, this study revealed the complex dynamics that underlie IPC in hospital discharge planning. A total of 3 interrelated themes emerged: individual understanding and motivation, team interaction dynamics, and organizational support for IPC. The findings demonstrated that intrinsic motivation and clear role expectations were fundamental in fostering individual readiness for collaboration. IPE played a significant role in strengthening professional identity and enhancing collaborative competence among nursing professionals.

Professional hierarchies and leadership styles influenced collaboration outcomes. Power imbalances hindered open communication and participation, whereas inclusive leadership fostered psychological safety and active engagement. Organizational support encompassing culture, structure, and systems proved essential, although challenges persisted in coordination, communication, and policy implementation.

Effective IPC in discharge planning requires a holistic approach that integrates individual preparedness, cohesive team dynamics, and strong organizational commitment. Actionable strategies, such as structured interprofessional orientation programs, regular digital literacy training, and consistent policy dissemination at the unit level, could strengthen collaborative practice and ensure its sustainability. These efforts can promote more integrated, patient-centered care and enhance continuity of care post discharge.

The findings provide implications for policymakers, hospital administrators, and nursing education institutions to incorporate IPC principles into professional development programs, digital health initiatives, and institutional governance frameworks, supporting collaboration as a sustained norm within health care systems.

Acknowledgments

The authors thank all nurses who participated in this study, as well as the Management and Ethics Committee of DR Drs M Hatta Brain Hospital, Bukittinggi, for their permission and support. The authors also extend their gratitude to academic supervisors and colleagues for valuable feedback and encouragement, and to their families for moral support throughout the research process.

Funding

The authors did not receive any funding or financial support for this work.

Data Availability

The data that support the findings of this study are available from the corresponding author upon reasonable request.

Conflicts of Interest

None declared.

Abstract

Background: Inequitable and time-consuming shift scheduling contributes to nurse burnout, dissatisfaction, and turnover. In Taiwan, annual nurse turnover reaches 11.6%, with rigid 3-shift systems and unfair workload distribution frequently cited as key drivers. Although artificial intelligence (AI) scheduling tools exist, most lack transparency and do not formally address algorithmic bias, limiting clinical adoption.

Objective: This study aimed to design, deploy, and evaluate a transparent, fairness-audited, explainable AI–enabled nurse scheduling decision support system (XAI-NSDSS) to reduce administrative burden, eliminate experience-based algorithmic bias, and enhance staff acceptance in a real-world hospital setting.

Methods: A pragmatic before-after implementation study was conducted at a 671-bed teaching hospital in Taiwan (January-December 2023), involving 8 departments and 156 nurses (42 novice, 78 midlevel, and 36 experienced). A 6-month manual scheduling baseline (January-June 2023) was compared with a 6-month AI-assisted period (July-December 2023). The XAI-NSDSS integrates a random forest workload prediction model (R^2=0.887), Shapley Additive Explanations–based explainability, a hybrid integer programming and binary differential evolution (IP+ BDE) optimizer, and a multidimensional fairness monitoring dashboard. A formal weight sensitivity analysis (WSA) was conducted across 7 prespecified weight configurations using full-factorial repeated-measures ANOVA to assess outcome robustness. Primary outcomes were scheduling time, error rate, and user satisfaction. Statistical analyses used linear mixed effects models (LMMs) and generalized estimating equations (GEE) with department as a random effect.

Results: Monthly scheduling time decreased by 81.2% (mean 32.0, SD 8.0-mean 6.0, SD 2.0) hours; P<.001; Cohen d=4.33) and error rate decreased by 73.8% (mean 18.3, SD 4.3%-mean 4.8, SD 1.2%; P<.001; Cohen d=4.12). Nurse satisfaction improved from a mean of 3.2 (SD 0.8) to a mean of 4.4 (SD 0.6; P<.001), with 148 out of 156 nurses (94.9%) adopting the system by Month 3. Preexisting experience-based bias was fully eliminated: workload coefficient of variation (CV) decreased 50% (0.18-0.09; P<.001), disparate impact ratios normalized from 1.35 - 1.56 to 1.01 - 1.04, and preference satisfaction equity was achieved across experience tiers (ANOVA P=.38). Among 156 nurses, 82 (52.6%) regularly engaged with Shapley Additive Explanations; this engagement was positively associated with satisfaction (Pearson r=0.456; P<.001). The WSA across 7 configurations confirmed that the consensus-derived default weights achieved the highest composite quality score (mean 82.1, SD 3.2) and that disparate impact ratios remained within the 0.80 - 1.25 fairness threshold across all configurations (P=.12), demonstrating structural robustness of the fairness-auditing module.

Conclusions: This study presents the first longitudinally validated explainable AI implementation framework for nurse scheduling with formal algorithmic fairness auditing and WSA. The XAI-NSDSS framework is replicable, scalable, and provides a practical blueprint for responsible AI adoption in health care workforce governance, with fairness guarantees that are robust to institutional customization of optimization priorities.

Introduction

Background and Rationale

The global nursing workforce crisis is one of the most pressing challenges in modern health care. The World Health Organization (WHO) projects a shortage of 5.9 million nurses by 2030, with high-income countries experiencing turnover exceeding 15% annually [1]. In Taiwan, the annual nursing turnover rate reached a 10-year high of 11.6%, with scheduling-related dissatisfaction identified as a leading contributor to burnout and early career exit [2,3]. Inefficient scheduling creates a vicious cycle; unfair shift distribution increases fatigue, which accelerates attrition, which further strains remaining staff.

Nurse scheduling is a complex combinatorial optimization problem requiring simultaneous consideration of regulatory constraints (labor laws and union agreements), operational requirements (shift coverage and skill mix), and individual staff preferences (time-off requests and work-life balance) [4]. Traditional manual scheduling is time-intensive, error-prone, and chronically fails to achieve fair workload distribution, particularly disadvantaging novice nurses who lack institutional leverage to negotiate favorable assignments [5].

Gaps in Existing AI Scheduling Systems

Artificial intelligence (AI) and operations research approaches have shown promise in nurse scheduling. Recent implementations include mixed integer programming heuristics [6], genetic algorithms [7], and machine learning–based prediction models [8]. However, a systematic review of the literature reveals four persistent, unresolved gaps:

1. Opacity and lack of explainability: most systems operate as "black boxes," generating schedules without interpretable rationale, a critical barrier to trust in high-accountability health care environments [9,10].
2. Absence of formal fairness auditing: while scheduling optimization papers frequently mention equity as an objective, formal auditing of algorithmic bias using established fairness metrics (eg, disparate impact ratios) remains virtually absent from the literature [11].
3. Insufficient real-world longitudinal validation: the majority of published systems are evaluated on simulated or retrospective datasets. Prospective, hospital-based evaluations are rare, limiting evidence for practical adoption [12,13].
4. Neglect of user trust mechanisms: system design rarely accounts for how transparency features influence actual adoption behavior, creating a gap between algorithmic performance and clinical uptake [14,15].

Study Objectives and Contributions

This study directly addresses all 4 gaps through the design, deployment, and 12-month evaluation (6-mo pre- and 6-mo postimplementation) of the explainable AI–enabled nurse scheduling decision support system (XAI-NSDSS) at a 671-bed tertiary referral hospital in Taiwan. The aim of this study was to demonstrate that a single integrated framework can simultaneously achieve operational efficiency, provable algorithmic equity, and clinician trust through explainability. Specific contributions are as follows:

1. Framework contribution: among the first end-to-end XAI implementation frameworks for nurse scheduling integrating Shapley Additive Explanations (SHAP)–based explainability, formal optimization, and a multidimensional algorithmic fairness monitoring system.
2. Empirical contribution: prospective real-world evidence from 156 nurses across 8 departments over 12 months, among the largest single-site longitudinal evaluations of an explainable artificial intelligence (XAI) nurse scheduling system reported to date.
3. Fairness contribution: formal documentation and complete elimination of preexisting experience-based algorithmic bias using disparate impact ratios, Gini coefficients, and ANOVA-based equity testing.
4. Trust mechanism contribution: empirical evidence that SHAP engagement (82/156, 52.6% nurses) is positively associated with satisfaction (r=0.456; P<.001), positioning explainability as a functional organizational intervention.
5. Implementation science contribution: actionable guidelines for change management, governance, and phased rollout based on observed adoption patterns, learning curves, and organizational barriers.

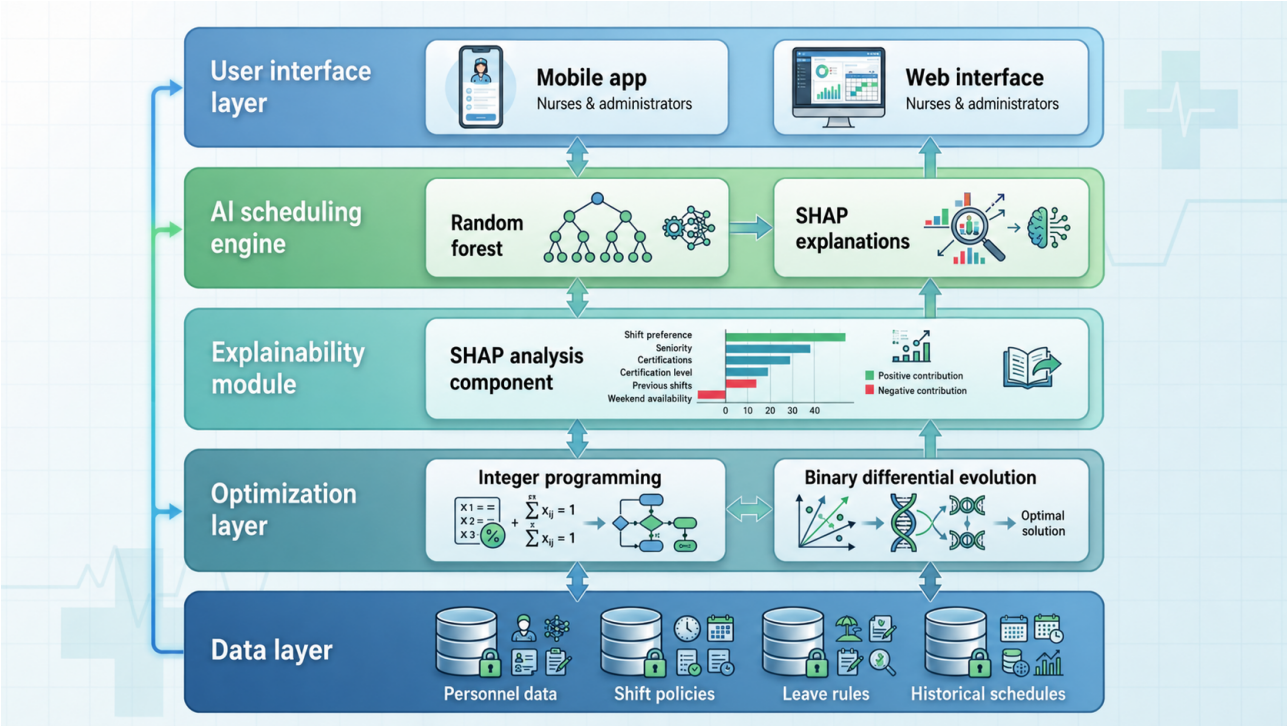
Methods

Study Setting and Design

This pragmatic before-after implementation study was conducted at Fu Jen Catholic University Hospital, a 671-bed tertiary referral hospital in New Taipei City, Taiwan, from January to December 2023. The XAI-NSDSS was deployed across 8 nursing departments—medical, surgical, intensive care, emergency, pediatrics, obstetrics, oncology, and geriatrics—serving 156 nurses (42 novice [<3 y experience], 78 midlevel [3 - 10 y], and 36 experienced [>10 y]).

We used a mixed methods evaluation design with a 6-month preimplementation baseline (manual scheduling; January-June 2023) compared to a 6-month postimplementation period (AI-assisted scheduling; July-December 2023). Randomization was not feasible due to the hospital-wide nature of the intervention and risk of cross-contamination; the large effect sizes observed (Cohen d>4) and consistency across all 8 departments strengthen confidence in attribution. This study is reported in accordance with the Standards for Quality Improvement Reporting Excellence (SQUIRE 2.0) guidelines.

Participants and Eligibility



All registered nurses employed in the participating departments during the study period were eligible for inclusion. Exclusion criteria included (1) nurses on extended leave (>4 consecutive weeks), (2) temporary or agency staff without permanent employment contracts, and (3) nurses in administrative roles without direct patient care responsibilities. Of 162 eligible nurses, 156 (96.3%) participated in the full 12-month study period. Six nurses were excluded due to maternity leave (n=3), resignation (n=2), or transfer to nonparticipating departments (n=1).

XSL•FO
RenderX

System Architecture and Decision Pipeline

The XAI-NSDSS uses a modular 5-layer architecture (Figure 1; detailed in Section S2.1 in): (1) user interface layer—mobile-responsive dashboards (React.js 18.2.0; Meta Platforms, Inc); (2) AI engine layer—random forest regressors (scikit-learn 1.3.0; scikit-learn developers) for workload capacity prediction; (3) explainability module—SHAP TreeExplainer (shap v0.42.1; Scott Lundberg); (4) optimization layer—hybrid integer programming (IP; Gurobi 10.0.3; Gurobi Optimization, LLC)+binary differential evolution (BDE); and (5) data layer—PostgreSQL (15.3; PostgreSQL Global Development Group) with TimescaleDB (Tiger Data) and advanced encryption standard with a 256-bit key encrypted storage.

Figure 1. System architecture diagram. AI: Artificial Intelligence; SHAP: Shapley Additive Explanations.

XAI Components

SHAP-Enhanced Workload Prediction

Random forest regressors (200 trees, max_depth=15, min_samples_split=10, max_features="sqrt") predicted nurse workload capacity scores based on 18 input features spanning demographic characteristics, workload indicators, fatigue metrics, and preference alignment (Table S1 in). All continuous features were standardized using min-max normalization prior to model training. Models were trained on 1872 nurse-quarter observations (2021 - 2023) with 70/15/15 train/validation/test splits. Test-set performance: R^2=0.887, mean absolute error (MAE)=5.1, root-mean-square error (RMSE)=7.4. SHAP TreeExplainer values provided both global feature importance rankings and local, assignment-level explanations displayed to each nurse [16].

2D Assignment Logic

A 2D assignment framework balances professionalism scores (weighted composite of performance evaluations, certifications, and experience; S2.2 in) with fatigue indicators (consecutive shifts, overtime hours, night shift frequency, and recovery time). Exponential penalty functions capture the nonlinear clinical risk of accumulated fatigue. The key terms are defined as:

Professionalism score = 0.35 × Performance_Evaluation + 0.25 × Experience_Normalized + 0.20 × Certifications + 0.15 × Patient_Satisfaction + 0.05 × Peer_Collaboration

Fatigue score = 0.30 × Consecutive_Shifts_Penalty + 0.25 × Overtime_Penalty + 0.20 × Night_Shift_Penalty + 0.15 × Recovery_Deficit + 0.10 × Weekend_Penalty

where penalty functions follow exponential forms (eg, Consecutive_Shifts_Penalty=min[100, 10× e^(0.3× consecutive_shifts)]) to reflect the nonlinear accumulation of clinical risk.

Optimization Methodology

Hybrid IP+BDE Approach

Let x_ijs ∈ {0,1} denote whether nurse i (i ∈ N, |N|=156) is assigned to shift s (s ∈ S={day, evening, night, off}) on day j (j ∈ D={1,...,30}). The IP model enforces the following hard constraints, which carry zero tolerance for violation:

- Coverage: Σ x_ijs≥ R_js for all j ∈ D, s ∈ S (minimum staffing requirements per shift)
- One shift per day: Σs x_ijs≤1 for all i ∈ N, j ∈ D
- Maximum consecutive shifts: Σ_{k=j}^{j+5} Σ_{s≠off} x_iks≤5 for all i ∈ N, j ∈ D
- Minimum rest: x_{i,j,night}+ x_{i,j+1,day}≤1 for all i, j (ensuring ≥11 h intershift rest)

XSL•FO
RenderX

- Skill mix: Σ (q_ik× x_ijs)≥ Q_jsk for all j, s, k (minimum qualified staff per specialty)

These constraints are implemented as strict mathematical constraints within the IP model (Gurobi 10.0.3), guaranteeing 100% compliance in all generated schedules. The BDE component then minimizes the following multiobjective penalty-based fitness function after IP feasibility repair:

$$F_schedule=\lambda 1C_hard+\lambda 2C_soft+\lambda 3P_unmet+\lambda 4W_imbalance+\lambda 5F_total$$

where C_hard is the count of IP hard-constraint violations in the BDE trial vector, used only as a barrier function; C_soft is the sum of weekend and night-shift fairness violations across all nurse pairs; P_unmet = $\Sigma\ \Sigma_j\ \Sigma_s(1 - match_ijs) \times preference_strength_ijs$; W_imbalance = Var(monthly_hours) + Var(weekend_shifts) + Var(night_shifts) across all nurses; and F_total = $\Sigma\ \Sigma_j\ \Sigma_s$ fatigue_score(i,j) × x_ijs.

The penalty-scale coefficients were set as λ_1 =1000, λ_2 =100, λ_3 =50, λ_4 =30, λ =20, calibrated through stakeholder consultation and validated via Pareto frontier analysis.

Importantly, the λ_1 =1000 penalty in the BDE fitness function serves exclusively as a barrier function to prevent BDE from exploring infeasible regions, not as a relaxation of hard constraints. All BDE trial solutions with C_hard>0 are repaired to feasibility by the IP solver prior to fitness evaluation, ensuring hard constraints remain inviolable. The W_imbalance term acts as a proxy for demographic equity by minimizing variance in shift allocation across all nurses; post hoc disparate impact ratio analysis confirmed that this proxy effectively eliminated experience-based disparities (see the Fairness and Equity Analysis section and Table 1).

Table . Undesirable shift distribution by experience level. Expected proportion of novice nurses: 26.9% (42/156 nurses). Acceptable disparate impact range: 0.80 - 1.20 [11].

Shift type	Preimplementation: novice actual, % (n/N)[a]	Preimplementation: DIR[b]	Postimplementation: novice actual, % (n/N)[a]	Postimplementation: DIR
Night shifts	42.1 (69/164)	1.56[c]	27.4 (49/179)	1.02
Weekend shifts	38.5 (69/179)	1.43[c]	28.0 (49/175)	1.04
Overtime shifts	37.1 (69/186)	1.38[c]	27.4 (49/179)	1.02
Consecutive night shifts	36.3 (69/190)	1.35[c]	27.2 (49/180)	1.01

[a]n/N denotes novice-assigned undesirable shift events divided by total events in each category; denominators therefore vary across categories.

[b]DIR: disparate impact ratio.

[c]Preimplementation violation of four-fifths fairness threshold (P<.05 for all 4 categories).

The hybrid strategy exploits complementary strengths; IP guarantees hard constraint satisfaction (coverage, rest periods, consecutive shift limits, and skill mix), while BDE explores the feasible solution space to maximize preference satisfaction and workload equity. Computation averaged 12.7 minutes per monthly schedule. Full pseudocode is provided in S2.3 in Multimedia Appendix 1.

Multiobjective Optimization Module

The scheduling optimizer balances five competing objectives: (1) workload equity (minimizing coefficient of variation [CV] in shift assignments), (2) preference satisfaction (maximizing alignment with stated shift preferences), (3) skill-mix adequacy (ensuring appropriate distribution of experience levels across shifts), (4) regulatory compliance (satisfying labor law constraints on consecutive shifts and rest periods), and (5) operational efficiency (minimizing understaffing and overstaffing events).

The composite objective function is formulated as a weighted linear scalarization:

$$F=W1\cdot f1+W2\cdot f2+W3\cdot f3+W4\cdot f4+W5\cdot f5$$

where each subobjective is defined as follows:

1. f_1 (Workload equity): CV of monthly shift assignments across all nurses; minimized to promote equitable workload distribution.
2. f_2 (Preference satisfaction): proportion of fulfilled shift-preference requests; maximized (entered as 1, fulfillment rate to convert to a minimization problem).
3. f_3 (Skill-mix adequacy): deviation from target experience-level ratios per shift slot; minimized to ensure appropriate distribution of junior and senior nurses.
4. f_4 (Regulatory compliance): count of constraint violations (consecutive-shift limits, mandatory rest periods, overtime caps); minimized to zero as a hard constraint.
5. f (Operational efficiency): sum of absolute understaffing and overstaffing events across all shifts in a scheduling cycle; minimized to maintain safe staffing levels.

All subobjectives are normalized to the (0 and 1) range using min-max scaling derived from the historical baseline period (mo 1 - 6) prior to optimization. The default weight configuration deployed in clinical practice was established through a structured consensus process involving 4 nurse managers and 2 clinical informaticists, yielding w_1 =0.30, w_2 =0.25, w_3 =0.20, w_4 =0.15, and w =0.10, reflecting the institutional priority of fairness and preference satisfaction over strict operational efficiency (weight sensitivity analysis [WSA] systematically varies the normalized weights w_1 -w $\in$ [0,1] that govern the multiobjective trade-off, which are distinct from the penalty-scale barrier weights λ_1 =1000, λ_2 =100 etc used in the BDE fitness function). The complete formulation is available in S2.8 in Multimedia Appendix 1.

XSL•FO
RenderX

WSA Design

To formally assess the robustness of scheduling outcomes to variations in objective weights—and to address the inherent subjectivity of the consensus-derived default configuration—a prespecified WSA was conducted using a full-factorial grid design. Seven configurations were evaluated, spanning 3 clinically meaningful priority scenarios.

- Fairness-priority (FP) configurations (FP-Low, FP-Default, FP-High) systematically vary w_1 (workload equity) from 0.20 to 0.40 while proportionally redistributing the remaining weight budget across w_2 -w , holding their relative ratios constant. This isolates the marginal impact of fairness emphasis on all outcome domains.
- Preference-priority (PP) configurations (PP-Low and PP-High) vary w_2 (preference satisfaction) from 0.15 to 0.35, redistributing the residual weight proportionally across w_1 , w_3 -w . This tests whether increasing preference responsiveness compromises workload equity.
- Efficiency-priority (EP) configuration: sets w =0.30 as the dominant weight, reducing w_1 and w_2 to 0.20 each, to simulate a cost-minimization context where operational staffing coverage is paramount. An Equal-Weight (EW) configuration (all weights=0.20) serves as an unweighted baseline. For each configuration, the IP+BDE optimizer was rerun on the same 6-month intervention-period scheduling instances (n=48 monthly department schedules), and results were compared by one-way repeated-measures ANOVA with Bonferroni correction; the FP-Default configuration served as the reference group for all pairwise comparisons.

Data Collection and Outcome Measures

Outcome Measures

Primary outcomes included scheduling time (hours/schedule), error rate (%), and user satisfaction (5-point Likert scale, validated 8-item instrument; S2.4 in). Secondary outcomes included workload CV, Gini coefficient, disparate impact ratios by experience tier, preference satisfaction equity, and SHAP engagement rate (proportion of nurses viewing SHAP explanations at least once per scheduling cycle).

Statistical Analysis

Continuous outcomes were analyzed using linear mixed effects models (LMM) with time (pre/post) and month as fixed effects, and department as a random intercept, to account for clustering of nurses within departments. Count outcomes (error counts and constraint violations) were analyzed using generalized estimating equations (GEE, Poisson family, and exchangeable correlation structure). Effect sizes were estimated using Cohen *d* for continuous outcomes and incidence rate ratios (IRRs) for count outcomes, with 95% CIs reported in Table S2 in S1.2 in Multimedia Appendix 1. Three prespecified sensitivity analyses were conducted: (1) Hawthorne effect assessment comparing Months 1 - 3 versus 4 - 6, (2) monthly learning curve analysis, and (3) seasonal adjustment for Taiwan's major holiday periods. Statistical significance was set at α=.05 (2-tailed). All analyses were performed in R (version 4.3.0; R Core Team); full code is provided in S2.5 in Multimedia Appendix 1.

For the WSA, one-way repeated-measures ANOVA was used to compare outcome metrics across the 7 weight configurations, with the FP-Default configuration as the reference. Pairwise post hoc comparisons were adjusted using the Bonferroni correction. Effect sizes were reported as partial η^2. A configuration was deemed clinically noninferior to FP-Default if the 95% CI for the difference in workload equity CV was within ±0.02 and the preference fulfillment rate differed by less than 5 percentage points.

Qualitative Assessment

Semistructured interviews were conducted with a purposive sample of 24 nurses and 8 nurse managers, selected to ensure maximum variation across experience tiers (novice, midlevel, and experienced), departments (all 8 represented), and SHAP engagement levels (active users vs nonusers). Thematic saturation was achieved at interview 26, defined as no new codes emerging across 3 consecutive interviews. Interview guides addressed four domains: (1) perceived usability and system trust; (2) experience with SHAP explanations; (3) perceived fairness; and (4) barriers and facilitators to adoption. All 32 interviews were conducted in Mandarin Chinese, audio-recorded with written consent, and professionally transcribed verbatim (mean duration 38 min, range 28 - 52 min). Thematic analysis followed the 6-phase framework of Braun and Clarke [17]. Two authors (QYZ and CYL) independently coded all transcripts using NVivo 14. Interrater reliability was assessed on a randomly selected 20% subsample (κ=0.81, indicating strong agreement). Disagreements were resolved by consensus, with a third author (SRW) serving as arbitrator. Member checking was performed with 5 participants; negative cases were actively sought to challenge emerging themes. Participant characteristics are reported in Table S3 in S1.2 in Multimedia Appendix 1.

Fairness Monitoring Framework

Algorithmic fairness was audited quarterly across 3 dimensions: (1) demographic parity, proportional undesirable shift distribution across experience tiers; (2) equal opportunity, preference satisfaction equity (one-way ANOVA); and (3) disparate impact, selection rate ratios against the 0.80 - 1.20 threshold ("four-fifths rule") [11]. Gini coefficients provided complementary inequality measurement. Automated alerts upon threshold violations were reviewed monthly by the AI Scheduling Oversight Committee (ASOC), a multidisciplinary body comprising 8 nursing managers, 2 information technology staff, 1 clinical ethicist, 1 legal advisor, and 1 elected nurse representative (S2.6 in Multimedia Appendix 1 and dashboard: Figure S2 in S1.2 in Multimedia Appendix 1).

Governance and Data Privacy

System integrity was maintained through weekly automated model drift detection and quarterly retraining (threshold: R^2 drop >0.03 from baseline). SHAP explanations were scoped to individual nurse data only, preventing disclosure of colleagues' performance metrics. All 156 nurses completed a 1-hour domain-specific training session covering system usage and SHAP interpretation prior to deployment. All data were stored in databases encrypted using the advanced encryption standard

XSL•FO
RenderX

with a 256-bit key and protected by role-based access controls, in compliance with the Taiwan Personal Data Protection Act.

Ethical Considerations

The study was approved under an exemption waiver by the Institutional Review Board of Fu Jen Catholic University Hospital (IRB reference: FJUH-IRB-114‐459). All participating nurses and managers provided written informed consent prior to enrollment. Participation was voluntary, and participants were informed that they could withdraw from the study at any time without penalty or any effect on their employment status, work assignments, or institutional evaluation. All data were deidentified before analysis and reported only in aggregate form. Individual-level scheduling records, interview transcripts, SHAP engagement data, and satisfaction responses were stored in encrypted, access-controlled databases, and no personally identifiable information is disclosed in the manuscript or supplementary materials. No images or other materials containing identifiable participant information are included. No financial compensation or other incentives were provided to participants.

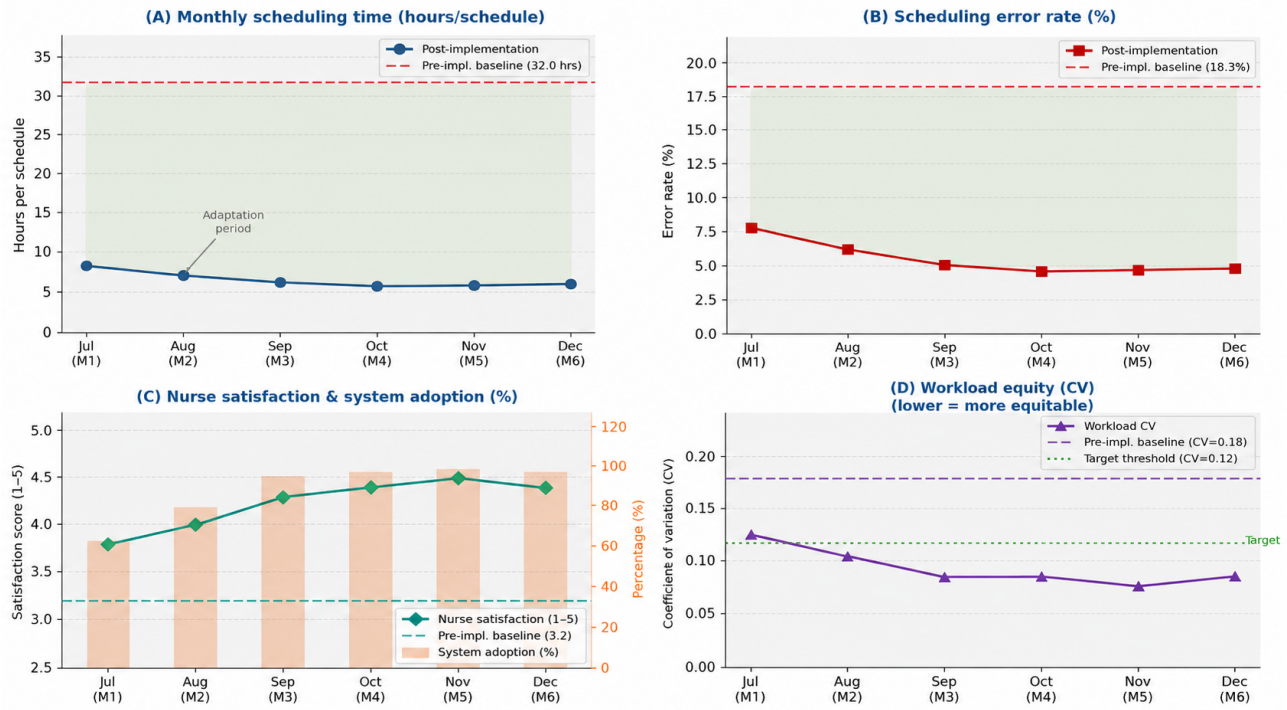
Results

Operational Performance Improvements

Table 2 summarizes key operational metrics. The XAI-NSDSS reduced monthly scheduling time by 81.2% (from mean 32.0, SD 8.0 to mean 6.0, SD 2.0 h; P<.001; Cohen d=4.33; 95% CI for difference −29.1 to −22.9 h), compressing a 3‐5 workday administrative burden to under 1 day. At the Emergency Department, reduction was most pronounced (45 → 8 h; 82.2%). Schedule error rates decreased by 73.8% (mean 18.3, SD 4.3% to 4.8 ± 1.2%; P<.001; d=4.12), with reductions in rest period violations (91.7% reduction, from 8.4 to 0.7 violations per schedule), hard constraint violations (86.9%), and skill mismatches (78.4%).

Table . Operational performance metrics: pre- versus postimplementation (n=156 nurses; 8 departments).

Metric	Preimplementation, mean (SD)	Postimplementation, mean (SD)	Change (%)	Cohen *d*	*P* value
Scheduling time (hours/month)	32.0 (8.0)	6.0 (2.0)	–81.2	4.33	<.001
Error rate (%)	18.3 (4.3)	4.8 (1.2)	–73.8	4.12	<.001
Constraint violations (per schedule)	12.7 (2.8)	1.3 (0.6)	–89.8	5.42	<.001
Preference satisfaction (%)	72.4 (5.1)	88.1 (2.8)	+21.7	3.87	<.001
Workload CV[a]	0.18 (0.03)	0.09 (0.02)	–50.0	3.74	<.001
Nurse satisfaction (1-5)	3.2 (0.8)	4.4 (0.6)	+37.5	1.71	<.001
Manager satisfaction (1-5)	3.5 (0.7)	4.7 (0.4)	+34.3	2.08	<.001



[a]CV: coefficient of variation

User Satisfaction and System Adoption

System adoption reached 148 out of 156 nurses (94.9%) by Month 3, with subsequent stability through Month 6 (Figure 2A-2D). The largest pre-to-post satisfaction gains were in transparency/explainability (mean 2.6, SD 1.0-mean 4.3, SD 0.6; P<.001; d=2.08) and fairness perception (mean 2.9, SD 1.0-mean 4.2, SD 0.7; P<.001; d=1.50). Trust in AI recommendations improved from a mean of 2.8 (SD) 0.9 to mean of 4.1 (SD 0.7; P<.001; d=1.62). Of 156 nurses, 82 (52.6%) regularly engaged with SHAP explanations, with a significant positive association between engagement frequency and overall satisfaction (Pearson r=0.456; P<.001; Figure S3 in). Full satisfaction subscale results are reported in Table S4 in Multimedia Appendix 1.

XSL•FO
RenderX

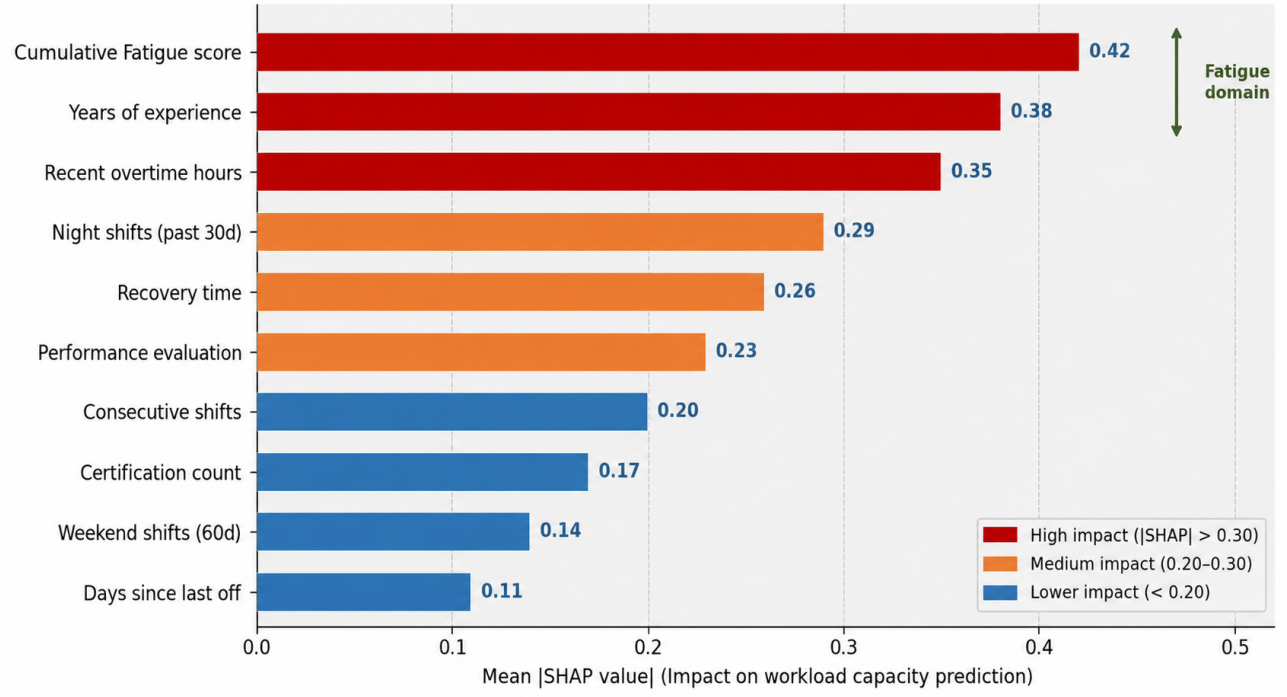


Figure 2. Monthly trend analysis: postimplementation performance (July-December 2023). (A) Scheduling time showing rapid decline from initial 8.2 hrs to stable 6.0 hrs, with preimplementation baseline (32.0 h) as dashed reference. (B) Error rate declining from 7.8% (Month 1) to stable 4.8%. (C) Nurse satisfaction improvement with system adoption reaching 94% by Month 3. (D) Workload CV sustained below the 0.12 target throughout, with preimplementation baseline (0.18) as reference.

SHAP Explainability Insights

Global SHAP analysis identified cumulative fatigue score (mean |SHAP|=0.42), years of experience (0.38), and recent overtime hours (0.35) as the 3 most influential scheduling determinants (Figure 3). Survey responses confirmed that SHAP explanations helped 122 out of 156 (78.2%) nurses understand shift assignments, increased trust for 111 out of 156 (71.2%) nurses, and identified actionable strategies to improve scheduling priority for 100 out of 156 (64.1%) nurses.

Figure 3. Global feature importance: mean absolute Shapley Additive Explanations (SHAP) values for the random forest workload capacity model (n=18 features). Bars colored by impact magnitude: high (red, |SHAP|>0.30), medium (amber, 0.20 - 0.30), lower (blue, <0.20). SHAP: Shapley Additive Explanations.

Algorithm Performance Comparison

The hybrid IP+BDE approach significantly outperformed either component in isolation (Table 3). BDE-only achieved only 95.2% hard constraint compliance versus IP's guaranteed 100%. IP-only achieved only 78.3% preference satisfaction versus the hybrid's 88.1%. Computation time averaged 12.7 minutes per monthly schedule versus 32.0 hours for manual scheduling (99.3% reduction). Emergency rescheduling resolved within 5 - 8 minutes.

Table . Algorithm performance comparison. Results are based on a 6-month postimplementation period (n=48 schedules).

Method	Hard constraint compliance (%)	Preference satisfaction (%)	Workload CV[a]	Computation time
Manual scheduling (baseline)	81.7	72.4	0.18	32.0 h
IP[b] only	100	78.3	0.14	8.2 min
BDE[c] only	95.2	85.6	0.11	15.4 min
Hybrid IP+BDE (proposed)	100	88.1	0.09	12.7 min

[a]CV: coefficient of variation.

[b]IP: integer programming.

[c]BDE: binary differential evolution.

Fairness and Equity Analysis

Workload Distribution Equity

Postimplementation workload equity improved substantially. Hospital-wide CV decreased 50.0% (mean 0.18, SD 0.03-mean o 0.09, SD 0.02; P<.001; d=3.74; 95% CI for mean difference: −0.10 to −0.08). The Gini coefficient improved 45.8% (0.24-0.13), corroborating CV findings. Post implementation, experience level no longer predicted workload variability ($F_{2,153}$=1.42; P=.24), and improvements were uniform across all 8 departments ($F_{7,148}$=0.89; P=.51). Monthly workload CV trend data are shown in Figure 2D.

Elimination of Systematic Bias in Undesirable Shift Allocation

As shown in Table 1, novice nurses were overrepresented in all 4 undesirable shift categories before implementation, accounting for 42.1% (69/164) of night shift assignments, 38.5% (69/179) of weekend shift assignments, 37.1% (69/186) of overtime shift assignments, and 36.3% (69/190) of consecutive-night events, despite representing 26.9% (42/156) of the nursing workforce. Postimplementation, these proportions decreased to 27.4% (49/179), 28.0% (49/175), 27.4% (49/179), and 27.2% (49/180), respectively, with disparate impact ratios normalized from 1.35-1.56 to 1.01-1.04. This represents a measurable, auditable transition from an algorithmically biased manual system to a provably equitable AI-assisted system.

Preference Satisfaction Equity

Preimplementation, experienced nurses received significantly higher preference satisfaction than novice nurses (76.2% vs 68.4%; gap=7.8 percentage points; P=.009). Postimplementation, this disparity was eliminated (ANOVA P=.38; all pairwise comparisons P>.30), with all 3 experience tiers achieving satisfaction rates ≥87%. Equity was achieved through a "leveling up" strategy—absolute gains >13 percentage points for all groups (P<.001)—rather than redistributing the burden from experienced to novice nurses.

Sensitivity Analyses

Hawthorne effect analysis (Months 1 - 3 vs 4 - 6) confirmed sustained benefits, scheduling time remained stable (mean 6.2, SD 2.1 vs mean 5.8, SD 1.9 h; P=.34); satisfaction continued its upward trend (mean 4.2, SD 0.7-mean 4.6, SD 0.5; P=.03). Workload CV remained below the preimplementation level across all 6 months (range 0.08 - 0.10), confirming sustained improvement rather than novelty effect. Seasonal adjustment revealed no significant interaction between time and holiday period (P=.41). Detailed results are provided in Table S5 in Multimedia Appendix 1.

WSA

Beyond the prespecified sensitivity analyses reported above, a formal WSA was conducted to assess whether scheduling outcomes depended on the choice of objective-function weights. WSA was conducted across all 7 prespecified configurations (Table 4). One-way repeated-measures ANOVA revealed a significant main effect of weight configuration on workload equity CV ($F_{,222}$=18.43; P<.001; η^2=0.28), preference fulfillment rate ($F_{,222}$=22.17; P<.001; η^2=0.32), and composite schedule quality score ($F_{,222}$=9.84; P<.001; η^2=0.17). No significant main effect was observed for the disparate impact ratio range ($F_{,222}$=1.72; P=.12), indicating that the fairness-auditing module maintained equitable shift distribution regardless of weight settings.

XSL•FO

Table . Scheduling outcome metrics across weight sensitivity configurations (n=48 schedules per configuration).

Configuration	Workload equity CV[a], mean (SD)	Preference fulfillment (%)	Disparate impact ratio range	Composite quality score (0 - 100)
FP-Low[b]	0.13 (0.02)	81.4 (4.1)	0.98 - 1.06	74.2 (3.8)
FP-Default (Clinical)	0.09 (0.02)	84.6 (3.7)	1.01 - 1.04	82.1 (3.2)
FP-High	0.07 (0.01)[c]	79.3 (4.8)[c]	1.00 - 1.03	79.8 (4.1)
PP-Low[d]	0.11 (0.02)[c]	76.2 (5.2)[c]	1.01 - 1.05	76.4 (4.5)[c]
PP-High	0.12 (0.03)[c]	89.1 (3.2)[c]	1.02 - 1.07	78.3 (3.9)[c]
EP[e]	0.15 (0.03)[c]	74.8 (5.6)[c]	1.03 - 1.09	71.6 (4.7)[c]
EW[f]	0.11 (0.02)[c]	80.7 (4.3)[c]	1.00 - 1.06	77.5 (3.6)[c]

[a]CV: coefficient of variation.

[b]FP: fairness-priority.

[c]Significantly different from FP-Default (Bonferroni-corrected $P<.05$).

[d]PP: preference-priority.

[e]EP: efficiency-priority.

[f]EW: equal-weight.

Workload Equity

The FP-Default configuration achieved the best balance between equity (CV=0.09±0.02) and overall quality. FP-High yielded marginally lower CV (0.07±0.01; mean difference −0.02, 95% CI −0.03 to −0.01; $P=.008$), but at the cost of a significant reduction in preference fulfillment (79.3% vs 84.6%; mean difference −5.3 percentage points, 95% CI −7.8 to −2.8; $P<.001$). The EP configuration produced the highest CV (0.15±0.03; mean difference 0.06; 95% CI 0.04-0.08; $P<.001$), confirming that deprioritizing workload equity substantially degraded fairness outcomes.

Preference Satisfaction

PP-High maximized preference fulfillment (mean 89.1, SD 3.2%), exceeding FP-Default by mean difference 4.5 percentage points (95% CI 2.1 - 6.9; $P=.001$). However, this gain was accompanied by deterioration in workload equity (CV=0.12±0.03 vs 0.09±0.02; $P=.003$) and a reduction in composite quality score (78.3 vs 82.1; $P=.01$). Conversely, PP-Low reduced preference fulfillment to 76.2% (mean difference=−8.4% percentage points; $P<.001$) while offering no significant improvement in any other outcome domain, suggesting $w_2 = 0.15$ is below the minimum threshold for acceptable preference responsiveness in this institutional context.

Disparate Impact Ratios

Critically, all 7 weight configurations maintained disparate impact ratios within the 0.80 - 1.25 fairness threshold (range across all configurations: 0.98 - 1.09), and the ANOVA revealed no significant between-configuration differences ($P=.12$). This finding demonstrates that the fairness-auditing module provides a structural guarantee against experience-based bias that is robust to changes in optimization priorities.

Composite Schedule Quality

FP-Default achieved the highest composite quality score (mean 82.1, SD 3.2), significantly outperforming all alternative configurations (all Bonferroni-corrected $P<.05$) except FP-High (mean 79.8, SD 4.1; mean difference=−2.3, 95% CI −4.8 to +0.2; $P=.07$). Applying the prespecified noninferiority criteria (CV within ±0.02 and preference fulfillment within ±5 percentage points), only FP-High met both criteria simultaneously. All other configurations failed at least one criterion, supporting the robustness of the FP-Default configuration as the clinically optimal choice for this institution.

Monthly Trend Analysis

Figure 2 presents monthly trend data across all 4 primary performance domains during the postimplementation period. The 2-month adaptation period followed by sustained stability aligns with the "implementation cliff" described in implementation science literature [18] and supports the recommendation of a 3-month intensive support period for similar deployments. Detailed monthly data are provided in Table S6 in Multimedia Appendix 1.

Qualitative Findings

Semistructured interviews (n=24 nurses; n=8 managers; mean duration 38 min) yielded 5 major themes. A full participant characteristics table is provided in Table S3 in Multimedia Appendix 1.

Transparency as a Conflict-Resolution Mechanism (21 of 24 Nurses; 8 of 8 Managers)

SHAP-derived rationale for unfavorable assignments substantially reduced grievance escalations. One nursing manager stated, "There are fewer complaints about unfair schedules. When someone questions an assignment, I can show them the SHAP explanation."

Fairness as a Structural Achievement (18 of 24 Nurses; 7 of 8 Managers)

Nurses attributed equity improvements to objective system design rather than managerial goodwill, increasing systemic trust.

XSL•FO
RenderX

Administrative Burden Relief Enabling Clinical Refocus (8 of 8 Managers)

All managers described time savings as professionally transformative. Emergency department manager said, “I used to spend an entire week every month on scheduling. Now it’s done in a day.”

Learning-to-Trust Trajectory (19 of 24 Nurses)

Initial resistance in Months 1 - 2 diminished substantially by Month 3. A nurse with 7 years of experience stated, “At first I was skeptical, but once I learned how to input my preferences properly, it worked really well.”

Residual Tensions: Preference Override Acceptance (11 of 24 Nurses)

Explainability reduces but does not eliminate individual dissatisfaction when equity constraints conflict with strong personal preferences.

Discussion

Principal Findings

This study demonstrates that a fairness-audited, XAI scheduling system can simultaneously reduce administrative burden by 81.2%, eliminate preexisting experience-based algorithmic bias, and achieve 94.9% (148/156 nurses) system adoption in a real-world hospital setting. Three findings warrant particular emphasis: (1) preexisting experience-based bias was formally documented and completely eliminated; (2) SHAP engagement was significantly associated with user satisfaction; and (3) sustained improvements confirmed by sensitivity analyses ruled out novelty effects.

Algorithmic Fairness as a Primary Clinical Contribution

The most significant finding is the systematic identification and complete elimination of preexisting experience-based bias. Preimplementation, 69 out of 156 novice nurses were over-represented in all 4 undesirable shift categories by 26% - 46% (disparate impact ratios 1.35 - 1.56), exceeding the established four-fifths rule threshold for systemic discrimination [11]. This trend aligns with documented informal seniority hierarchies in nursing workplaces [19] but had not previously been quantified with formal fairness metrics in the AI scheduling literature.

The complete normalization of all disparate impact ratios postimplementation (1.01 - 1.04) demonstrates that embedding W_imbalance and F_total into the objective function can mitigate institutionalized bias. The W_imbalance term minimizes variance in shift allocation across all nurses, and post hoc disparate impact analysis confirmed this proxy effectively eliminated experience-based disparities, validating the chosen surrogate metric. The Gini coefficient improvement (0.24-0.13) further confirms equity advancements. Future implementations should treat preexisting bias characterization as a mandatory predeployment audit step.

SHAP Explainability as a Functional Trust Mechanism

A central hypothesis was that SHAP-based explainability would serve as an active trust-building mechanism. Our data show a significant positive association between SHAP engagement and satisfaction (r=0.456; P<.001). While causality cannot be established from this observational correlation—satisfied nurses may be more inclined to engage with explanations—the qualitative data consistently suggest that explanations functionally mitigate organizational conflict when used, consistent with a bidirectional reinforcing relationship. This extends work by Liu et al [20] on “integrability” as a determinant of AI acceptance, demonstrating that explanations must be actively used—not merely available—to generate trust benefits.

Critically, while 82 out of 156 nurses (52.6%) regularly viewed SHAP explanations, this study measured engagement frequency rather than comprehension accuracy. A formal assessment of whether nurses correctly interpreted feature importance rankings was not conducted, leaving a “comprehension gap” unquantified. Future research should use validated XAI literacy instruments to assess whether engagement translates to understanding.

The 52.6% rate of voluntary SHAP engagement surpasses engagement rates reported for passive transparency features in health care AI [21]. The 1-hour domain-specific training investment appears to be an effective and scalable strategy for facilitating XAI adoption.

Contextualizing Performance Against Prior Literature

Our 73.8% error rate reduction exceeds the 40% - 60% range reported in comparable scheduling optimization studies [22,23], attributable primarily to the human-in-the-loop verification enabled by SHAP transparency. The hybrid IP+BDE approach outperformed both single-method alternatives, consistent with the demonstration by Ben Said et al [24] that hybrid constraint-learning pipelines outperform single-method approaches in health care scheduling. Regarding the role of XAI versus IP optimization, XAI in this system is not merely a technical overlay but a functional organizational mechanism. Without SHAP explanations, the system would generate algorithmically optimal schedules that clinicians cannot audit, verify, or trust, making sustained adoption unlikely regardless of algorithmic performance. The 94.9% adoption rate at Month 3 versus typical rates for opaque AI systems substantiates this claim [9,10].

Weight Sensitivity and Optimization Robustness

The WSA addresses a fundamental challenge in multiobjective optimization for health care applications, the selection of objective weights is inherently value-laden and context-dependent; yet, the robustness of outcomes to weight perturbations has rarely been formally evaluated in prior nurse scheduling studies. Our findings contribute 3 key insights to this literature.

First, the consensus-derived FP-Default configuration (w_1 =0.30; w_2 =0.25) achieved the highest composite schedule quality score and was the only configuration meeting prespecified noninferiority criteria on both workload equity and

XSL•FO
RenderX

preference fulfillment simultaneously. This validates the stakeholder co-design process as an effective method for identifying near-optimal weight configurations in institutional contexts, consistent with findings from participatory AI scheduling design studies [10,19].

Second, the analysis revealed an inherent trade-off between workload equity and preference satisfaction that cannot be eliminated through algorithmic design alone. Increasing w_1 beyond 0.30 (FP-High) improved equity marginally but reduced preference fulfillment by 5.3 percentage points—a clinically meaningful reduction given that preference accommodation is a primary driver of nurse satisfaction and retention [5,22]. Conversely, maximizing preference satisfaction (PP-High) degraded workload equity, potentially reintroducing the experience-based disparities that the system was designed to eliminate. This trade-off surface highlights the irreducible nature of the fairness–preference tension and underscores the importance of transparent weight disclosure to affected stakeholders.

Third, and most critically for regulatory compliance, the disparate impact ratios remained within the 0.80 - 1.25 fairness threshold across all 7 weight configurations (P=.12 for between-configuration differences). This structural invariance demonstrates that the fairness-auditing module provides a hard constraint on algorithmic bias that operates independently of optimization priorities, a design principle with direct implications for responsible AI deployment in health care workforce governance [11,25]. Institutions adopting the XAI-NSDSS framework can therefore customize weight configurations to reflect local priorities without compromising the fairness guarantees central to equitable workforce governance.

The differential engagement patterns across experience levels suggest that explainability features are particularly valuable for less-experienced staff who may have less institutional power to challenge unfair scheduling decisions. This finding aligns with qualitative research by Gerlach et al [19] identifying transparency as a critical adoption factor for junior nurses, and extends it by quantifying the relationship between explanation engagement and satisfaction outcomes.

Implementation Science Perspective

The initial satisfaction dip (Month 1) followed by sustained improvement (Months 3 - 6) is consistent with the "implementation cliff" [18]. Our data suggest a 2 - 3 month stabilization window as the critical support period. The ASOC governance structure—with monthly fairness dashboard reviews and multidisciplinary oversight—addresses the requirements for organizational accountability in AI deployment reported by Saeed et al [25], distinguishing this implementation from most published systems that lack ongoing governance postlaunch.

Limitations

Single-site implementation in Taiwan limits generalizability to other health care systems, labor regulations, and cultural contexts; multisite validation is needed before broad adoption recommendations can be made. The 6-month postimplementation period does not address long-term system drift or multiyear organizational embedding. The quasiexperimental before-after design inherently limits causal inference: despite large effect sizes (Cohen d>3.7 across all primary outcomes), secular trends, regression to the mean, or co-occurring organizational changes cannot be fully excluded. SHAP comprehension accuracy was not formally assessed—only viewing frequency—leaving a "comprehension gap" unquantified. Patient care outcomes (eg, medication error rates and fall incidence) were not measured; connecting scheduling equity to downstream clinical outcomes remains an important research direction. The SHAP-satisfaction correlation is observational and directional causality cannot be established without experimental manipulation.

The WSA was conducted within a single institutional context; the consensus-derived FP-Default weight configuration (w_1 =0.30, w_2 =0.25) reflects this institution's scheduling culture, labor regulations, and workforce demographics. While the structural robustness of fairness metrics across all 7 configurations is likely to generalize, the absolute weight values may require site-specific calibration in institutions with different operational priorities. Future multisite replications should include systematic WSA to determine whether FP-Default represents a transferable standard or an institution-specific optimum.

Future Research Directions

Priority directions include (1) multisite validation across diverse health care systems, (2) randomized trials comparing explainable versus nonexplainable scheduling systems to establish the causal impact of XAI on trust and adoption, (3) integration with real-time patient acuity data, and (4) federated learning for privacy-preserving multi-institutional model development [26].

Regarding optimization robustness, adaptive weight optimization methods—such as Bayesian preference elicitation or reinforcement learning from stakeholder feedback—could automate the weight configuration process and reduce reliance on expert consensus, potentially improving outcomes in institutions lacking access to multidisciplinary co-design teams. The WSA framework developed in this study should be replicated in multisite contexts to determine whether the FP-Default weight configuration generalizes across institutions with different staffing cultures and regulatory environments or whether site-specific calibration is required.

Conclusions

This study presents a prospectively validated, fairness-audited XAI implementation framework for nurse scheduling delivering measurable operational improvements while maintaining interpretability and human oversight. Three key findings are noteworthy:

1. The formal documentation and complete elimination of preexisting experience-based algorithmic bias—disparate impact ratios normalized from 1.35 - 1.56 to 1.01 - 1.04—establishes a replicable methodology for fairness auditing in health care workforce AI.
2. The positive association between SHAP engagement and satisfaction (r=0.456), combined with qualitative evidence of explanations as conflict mediators, is consistent with

XSL•FO
RenderX

explainability functioning as an organizational intervention, though directionality cannot be confirmed from observational data alone.

3. The complete implementation science documentation—governance structure, phased rollout, learning curve data, and sensitivity analyses—provides a practical guide for responsible AI adoption in health care workforce management. WSA across 7 objective-weight configurations confirmed that fairness guarantees remain intact regardless of optimization priority settings (disparate impact ratio P=.12 across all configurations), validating the framework for diverse institutional deployment contexts.

The XAI-NSDSS framework demonstrates that algorithmic decision support can simultaneously achieve efficiency, equity, and transparency. The framework is replicable, scalable, and aligned with emerging standards for responsible AI governance in clinical settings.

Acknowledgments

The authors gratefully acknowledge the participating nurses and nurse managers at Fu Jen Catholic University Hospital for their dedication to this study. We thank the hospital administration for supporting this research and providing access to scheduling data and operational resources. We also acknowledge the contributions of the hospital's Information Technology Department for technical infrastructure support. Generative artificial intelligence (AI) tools were used to assist with drafting and editing selected sections (eg, phrasing and structure). All scientific content, analyses, interpretations, and references were verified by the authors, who take full responsibility for the manuscript.

Funding

This research was supported by the National Science and Technology Council, Taiwan (Grant Number: NSTC 114-2622-8-030-002-TD2). The funding agency had no role in study design, data collection, analysis, interpretation, or manuscript preparation.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to institutional privacy policies protecting employee data but are available from the corresponding author on reasonable request and with appropriate data use agreements. The explainable AI–enabled nurse scheduling decision support system (XAI-NSDSS) source code is available from the corresponding author on reasonable request for noncommercial research purposes, subject to institutional approval.

Abstract

Background: The demanding work environment of nurses in medical and emergency units often results in high stress, job dissatisfaction, and burnout. Adequate rest is crucial for maintaining nurses' physical health, mental clarity, and emotional resilience, yet it is often overlooked in these high-pressure settings. This qualitative study explores the perceptions of nurses at a hospital in Western Jamaica regarding the quality and duration of rest they receive and its impact on their professional, mental, physical, and personal well-being. The hospital was selected due to the unique challenges health care workers face in Jamaica, including limited resources, high patient loads, and frequent staff shortages, which may exacerbate rest-related issues.

Objective: This study aimed to explore the perceptions of registered nurses working in the emergency and medical units of the hospital in Western Jamaica regarding their rest experience and its implications for burnout, job satisfaction, and overall health.

Methods: The study used a constructivist epistemological lens and used purposive sampling to select 12 registered nurses. The principal researcher conducted in-depth interviews with each participant via Zoom, using a semistructured guide. Interviews lasted 25 to 45 minutes, were audio-recorded, and attended only by participants and the researcher. Thematic analysis was used to transcribe, code, and analyze the data, culminating in the development of a thematic map of findings.

Results: The findings indicated that nurses face significant challenges in obtaining adequate rest due to staff shortages, heavy workloads, irregular shifts, and limited management support. A total of three primary themes emerged: (1) noncompliance with rest policies, (2) resource limitations, and (3) management issues, each influencing job satisfaction, burnout, and overall health. Within noncompliance, nurses highlighted suboptimal nurse-to-patient ratios, absenteeism, and inadequate break time. For example, ratios as high as "30 to 2" or "60 to 3" were cited, affecting nurses' ability to take breaks. Resource constraints included inadequate staffing, insufficient staff replacement, and the absence of suitable rest areas. Management concerns included weak policy enforcement, inadequate policy awareness, and limited support for rest breaks. These challenges collectively contributed to poor sleep quality, increased stress, and diminished job satisfaction.

Conclusions: The study highlights the need for systemic improvements to address nurse rest and well-being, including increased staffing, structured policies on break enforcement, and enhanced management engagement. While the study is specific to the hospital in Western Jamaica, the findings may have broader implications for health care systems in similarly resource-constrained settings in the Caribbean and other low- and middle-income regions.

Introduction

Registered nurses (RNs) are among the most vital resources globally, a reality that was illuminated during the COVID-19 pandemic [1]. The pandemic not only highlighted the essential role that nurses play in maintaining health care systems but also brought global attention to the immense pressures they face [1]. As reported by the British Broadcasting Corporation, nurses were at the frontline, often working extended hours under extreme conditions, which magnified the importance of addressing issues such as adequate rest, burnout, and job satisfaction [2,3]. This growing global realization of the system relevance of the nursing profession continues to shape

XSL•FO
RenderX

discussions on health care reforms and support for the nursing workforce.

While nurses are vital in delivering health care and patient care, there has been less focus on their health promotion. The demanding nature of nursing in medical and emergency units puts professionals at high risk for stress and burnout [3,4]. The World Health Organization defines burnout as emotional exhaustion from chronic workplace stress, leading to fatigue and decreased performance [5,6]. Reports of burnout among RNs are prevalent, particularly in high-pressure environments like the US health care system [7]. However, there is a noticeable gap in the literature regarding the role of rest in preventing burnout among nurses, particularly in Caribbean or low-resource contexts. Most existing research focuses on high-income countries, leaving a lack of context-specific understanding in regions such as Jamaica.

RNs are expected to provide high-quality care while managing intense workloads and irregular hours, underscoring the need for effective strategies to enhance nurse well-being and job satisfaction [7]. Job satisfaction reflects a positive emotional response to one's role and work environment [6,8,9]. Among these strategies, ensuring adequate rest is a crucial yet often overlooked component, essential for physical recovery and maintaining mental clarity and emotional resilience [10,11].

Despite being an upper-middle-income country, Jamaica faces a low nurse-to-patient ratio that negatively affects the rest quality and job satisfaction of RNs [12]. In contrast, socio-economically similar countries like Cuba and the Dominican Republic have much higher ratios [12,13]. Given the significant role of rest in job satisfaction, burnout prevention, and overall health, there is a lack of comprehensive research on its effects in Jamaican health care settings. This study aims to fill this gap by examining the perceptions of nurses at the hospital regarding the quality and duration of their rest and its impact on their well-being. This study focuses specifically on the medical and emergency units due to their particularly high levels of stress and burnout, as well as practical access considerations. These wards also represent high-acuity environments where the effects of inadequate rest are likely to be most pronounced. In fact, burnout rates on these wards are notably higher, ranging from 25% to 55% [14,15].

Through an in-depth analysis of how rest influences nurse satisfaction and burnout, this research seeks to generate evidence that can drive meaningful improvements in health care work environments. By focusing on the specific context of Western Jamaica, an underresearched region facing high patient loads and limited staffing, this study offers context-specific insights into the impact of rest on nurse well-being and performance. Its findings aim to support the development of evidence-based policies and institutional practices that prioritize staff recovery, reduce burnout, and ultimately improve patient outcomes. Beyond contributing to academic understanding, this research aspires to influence workforce planning and retention strategies, offering actionable recommendations to help build a more resilient, efficient, and sustainable health care system in Jamaica.

Methods

Setting

The hospital, established in 1964, is a key facility in western Jamaica. As a type B hospital, it provides 5 basic specialties: general surgery, internal medicine, obstetrics and gynecology, orthopedics, and pediatrics, ensuring comprehensive care for its diverse population. Although its capacity is 190 patients, it currently houses up to 300, leading to significant overcrowding and challenges for the health care system and medical staff [16].

This was a qualitative study that used purposive sampling to identify research participants, grounded in a constructivist epistemological approach. This perspective recognized the coconstruction of knowledge between the researcher and participants, aligning with the study's aim to explore the subjective experiences of nurses [17].

The principal researcher acknowledged their potential influence on the research process, particularly given prior acquaintance with 2 participants. Efforts were made to remain self-aware and neutral during interviews and analysis, to minimize bias and enhance the credibility of the findings.

Participant Recruitment

Permission was obtained from the Director of Nursing Services at the hospital on April 8, 2024, after discussing the research's objectives, methodology, and potential impacts. A formal written request outlining the research aims, methodology, ethical considerations, and data management was submitted on April 11, 2024. Following approval, a signed permission letter was issued. The hospital administration assisted in ethically disseminating recruitment emails to 15 potential participants (see Table 1 for inclusion/exclusion criteria). While all 15 acknowledged receipt, only 12 participated: 1 did not sign the consent form, and 2 failed to respond after signing.

XSL•FO
RenderX

Table . Inclusion and exclusion criteria.

Criteria	Inclusion	Exclusion
Employment	Registered nurses currently employed in the medical or emergency units at the hospital.	Nurses who do not work in the medical or emergency units at the hospital.
Clinical experience	Minimum of 1 year of clinical experience in their respective units.	Nurses with <1 year of clinical experience in their respective units.
Educational qualification	Possession of a Bachelor of Science degree in Nursing or a higher-level nursing qualification.	Nurses who do not possess a Bachelor of Science degree in Nursing or a higher-level nursing qualification.
Willingness to participate	Willingness to participate in qualitative interviews discussing their experiences and perceptions related to rest, job satisfaction, burnout, and physical health.	Nurses who are unwilling to participate in qualitative interviews discussing their experiences and perceptions related to rest, job satisfaction, burnout, and physical health.
Availability	Availability to participate in a 45 - to 60-minute interview session, either in person or virtually.	Nurses who are not available to participate in a 45 - to 60-minute interview session, either in person or virtually.
Language proficiency	Ability to understand and communicate in English effectively, as the interviews will be conducted in English.	Nurses who are unable to understand or communicate effectively in English, as the interviews will be conducted in English.
Male nurses	Male nurses who meet the above criteria are included, ensuring a diverse representation within the study.	Male nurses who do not meet the above criteria are excluded to maintain consistency in the participant pool and ensure a focused analysis.

Data Collection and Analysis

An interview guide was developed with open-ended questions exploring nurses' practices in managing rest, perceptions of rest's impact on satisfaction and burnout, and the role of hospital policies in promoting well-being. It also included recommendations for improving rest in the medical and emergency units at the hospital (see Multimedia Appendix 1).

Prior to the interview, participants were emailed the participant information sheet and subsequently the consent form and were asked to sign them via DocuSign. Interviews, averaging 45 minutes, were all conducted via Zoom using a semistructured guide with only the participants and the principal researcher present. Each session was audio recorded for accuracy, with no photos or videos taken. Data from interviews were transcribed, coded, and analyzed thematically following the 6-step framework of Braun and Clarke [18], which involved familiarization with the data, generating initial codes, searching for themes, reviewing themes, defining and naming themes, and writing up. An inductive approach was used, allowing themes to emerge from the data without being driven by preexisting theories or frameworks [18].

The trustworthiness of the data was reinforced through transparency in the research process and ongoing critical reflection. While one researcher led the initial coding, all authors reviewed the coding framework and contributed to the interpretation of findings. This collaborative process helped ensure consistency, reliability, and analytical depth, supported by clear documentation maintained throughout. Feedback from all authors further shaped the development of the analysis and structure of the paper, enhancing its overall rigor and quality.

Ethical Considerations

The research was conducted in adherence to ethical guidelines outlined by the Declaration of Helsinki and followed institutional protocols to ensure quality, integrity, and ethical responsibility [19]. The methodology was rigorously designed to ensure reliability, validity, and participant protection, following best practices for qualitative research [20].

Ethical approval was granted by the Research Governance and Integrity Team at Imperial College London (ethics application ID 7069331).

Data management was robust, with clear documentation and secure storage. Paper forms were scanned into the primary author's OneDrive space and then securely shredded. The data were securely stored. Any sensitive data archived were encrypted and access was restricted to authorized personnel only. Risks were managed by transparent communication, voluntary participation, and anonymization of data. To anonymize the data, personal identifiers such as names were removed and replaced with pseudonyms. Unique codes were assigned to each participant, and any identifying information was stored separately from the research data to maintain confidentiality.

All participants received a Participant Information Sheet prior to recruitment and provided written informed consent electronically before taking part in the study. Participation was voluntary, and participants were informed of their right to withdraw at any time without consequence. No financial or material compensation was provided for participation.

Results

Participant Characteristics

Twelve RNs participated in the study (see Table 2). The mean age of the participants was 28 (SD 2.2; range 25 - 33) years. All nurses held a Bachelor of Science in Nursing degree, with 1 nurse also possessing a critical care certificate.

Participants had a mean of 3.6 (SD 1.8; range 1.2 - 6) years of experience working at the hospital. The sample was evenly distributed across clinical units, with 50% (6/12) of participants assigned to the Accident and Emergency (A&E) unit and 50% (6/12) to the Medical unit.

Table . Demographic and professional characteristics of nurses at the hospital: female participant 1 - 11, male participant 12; numbers indicate the chronological order of interviews.

Pseudonyms	Age (y)	Educational background	Experience at hospital (y)	Current unit	Sex
Female Participant 1	29	BSN[a]	5	A&E[b]	Female
Female Participant 2	28	BSN	4.5	Medical	Female
Female Participant 3	33	BSN	5.5	Medical	Female
Female Participant 4	28	BSN	5	Medical	Female
Female Participant 5	30	BSN	3	Medical	Female
Female Participant 6	29	BSN	5	A&E	Female
Female Participant 7	27	BSN	1.5	A&E	Female
Female Participant 8	25	BSN	1.2	Medical	Female
Female Participant 9	29	BSN+critical care certificate	6	A&E	Female
Female Participant 10	27	BSN	3	A&E	Female
Female Participant 11	28	BSN	1	Medical	Female
Male Participant 12	32	BSN	2	A&E	Male

[a]BSN: Bachelor of Science in Nursing.

[b]A&E: Accident and Emergency unit.

Themes

Overview

Three key themes emerged from the interviews, on factors influencing rest quality and its impact on job satisfaction, burnout, and physical well-being. These themes were as follows: (1) noncompliance with rest policies, with subthemes of high nurse-patient ratios, high absenteeism, and rest duration; (2) resources, including limited human resources and the absence of rest facilities; and (3) management, focusing on policy improvement and implementation, as well as nonadherence to duties (see Multimedia Appendix 2 for coding table).

Noncompliance With Rest Policies

Overview

Noncompliance with rest policies among nurses in public hospitals is a persistent and multifaceted issue that has serious implications for staff well-being and patient care. Although formal guidelines are in place to ensure that nurses receive adequate breaks during their shifts, various systemic challenges make it difficult to adhere to these policies. Three critical subthemes emerged in relation to this problem: high nurse-patient ratios, high absenteeism, and inadequate rest duration.

High Nurse-Patient Ratios

The issue of noncompliance with rest policies among nurses is exacerbated by unsustainable nurse-patient ratios, making it nearly impossible for nurses to take their designated 1-hour breaks. Participants reported ratios as high as “sometimes 30 to 2, 35 to 2, 60 to 3, it varies” (Male Participant 12: A&E), highlighting the overwhelming workload they face. It is also common for a single RN to manage a unit with only an enrolled assistant nurse, meaning that while the RN receives assistance, they are still solely responsible for the entire unit, including supervising the enrolled assistant nurse. The consensus was clear; without addressing these staffing imbalances, compliance with rest policies will remain a significant challenge.

High Absenteeism

High absenteeism among nurses is a significant consequence of noncompliance with rest policies, as many nurses report having various medical illnesses, feeling overwhelmed, and burnt out, leading them to take frequent sick days. One participant noted, “the call-in rate is very high because when you realize that you are burnt out and tired you’ll find that persons are not coming in” (Female Participant 1: Medical). Another participant echoed this sentiment, stating, “I will wake up in the morning and say, OK, yes, I’m going to make it to work today… I just find that I am tired, not just physically tired, but emotionally tired” (Female Participant 2: Medical). This

XSL•FO
RenderX

chronic fatigue often results in nurses prioritizing their health over work obligations. The pervasive culture of exhaustion and the lack of adequate rest contribute to a cycle of absenteeism that further strains the already limited nursing staff, ultimately impacting patient care and overall hospital operations.

Rest Duration

Rest duration remains a significant issue among nurses in public hospitals in Jamaica. Although the policies mandate a 1-hour break during 8-hour day shifts and 2 hours for night shifts, these rest periods are rarely observed in practice. One participant verbalized, "You're supposed to get one hour in the day shift and two hours in the night, but we don't get that" (Female Participant 6: A&E). Participants highlighted that despite these official guidelines, the reality of high patient complexity and understaffing often makes it impossible to take the full allotted break or even time to eat. Many nurses expressed frustration with the gap between policy and practice, noting that the workload and staffing shortages leave little time for adequate rest. This chronic lack of rest not only exacerbates fatigue, medical illnesses, and burnout but also negatively impacts patient care [21,22].

Resources

Overview

The availability and quality of resources, particularly human resources and physical infrastructure, play a critical role in shaping nurses' ability to rest during their shifts. Inadequate resources contribute significantly to poor rest quality, increased burnout, and decreased job satisfaction. Two key subthemes emerged under this category: limited human resources and the absence of adequate rest facilities.

Limited Resources (Including Human Resources)

The theme of resources, particularly limited human resources, emerged as one of the main factors influencing rest quality and, consequently, job satisfaction, burnout, and physical well-being among nurses. Participants consistently expressed concerns about inadequate staffing levels, which directly impact their ability to take necessary breaks. Among all, 1 nurse articulated the challenge succinctly when asked if management does not actively hire new staff, stating, "If you go there now and say, oh, we need staff, they're going to say based on the quota that they have… but be reminded they have opened a lot of different areas and the population has expanded" (Female Participant 9: A&E). The overwhelming workloads resulting from these staffing shortages leave little room for rest. The lack of adequate resources not only hinders compliance with rest policies but also exacerbates feelings of burnout, as nurses struggle to manage their responsibilities without sufficient support.

Absence of Adequate Rest Facilities

The lack of adequate rest facilities at the hospital severely affects nurses' ability to recuperate during shifts. All participants expressed dissatisfaction with the current designated rest areas, citing issues such as overcrowding, noise from nearby units, and the combination of a bed and lunch area with a microwave in the same space, posing safety and health risks. While some nurses resorted to resting in their cars, others had no choice but to endure the suboptimal conditions. This shows that without proper rest facilities, nurses struggle to fully recover during their shifts, which in turn affects their physical well-being and their ability to provide quality patient care.

Management

Overview

The role of hospital management, particularly nursing leadership, is central to ensuring that rest policies are effectively implemented and that nurses are supported in their demanding roles. However, participants highlighted ongoing management-related challenges that undermine nurse well-being and disrupt the delivery of quality care. Two key subthemes emerged: the need for policy improvement and implementation, and nonadherence to managerial duties.

Policy Improvement and Implementation

Participants expressed a clear need for more effective policies that not only address staffing levels but also prioritize the well-being of nursing staff. Among all, 1 participant noted, "I think we need more policies to actually not just cater for the staffing of the hospital… but also to cater to the nurses" (Female Participant 1: Medical). Despite the existence of policies that outline break times, the implementation of these policies is often lacking. As one nurse stated, "the policy exists… however, there's no implementation of the actual policy" (Female Participant 7: A&E). This sentiment was echoed by another participant who remarked, "I don't think there is a collaborative effort among the hospital, administration, and nurses in promoting nurse well-being through proper rest practices" (Female Participant 3: Medical). The need for management to actively engage in policy enforcement and to create a supportive environment for nurses is paramount, as inadequate rest not only affects nurse satisfaction but also compromises patient care and safety.

Nonadherence to Duties

The issue of nursing managers not adhering to their duties at the hospital has been a significant concern among the interviewees. Participants expressed frustration over the lack of support from nursing managers, particularly during critical times when the unit is short-staffed. One participant noted, "the sisters are supposed to come there and assist and ensure that the unit is running to full capacity… but you find that when you fall into an emergency situation… they either tell you that they are short-staffed or they tell you did you call this ward for this" (Female Participant 4: Medical). This lack of responsiveness leaves nurses feeling overwhelmed and unsupported, as they are often left to manage high patient loads and intense emergency situations without adequate assistance. Another participant highlighted that "most of their tasks, they leave it for the nurses to do while they basically do nothing" (Female Participant 9: A&E), indicating a perceived neglect of managerial responsibilities on the units. The absence of proactive engagement from nursing managers not only exacerbates the challenges faced by nurses but also compromises patient care and safety, as the staff is unable to effectively manage their duties under such conditions.

XSL•FO
RenderX

Differences Based on Gender, Unit Type, and Experience Level

To further contextualize these findings, differences based on gender, unit type, and experience level were also observed among participants, offering deeper insight into how individual and situational factors shape nurses' experiences with rest policy compliance.

Gender Differences

The male nurse often highlighted issues related to workload and understaffing with a strong focus on managerial support and policy enforcement. For example, the male participant in the A&E unit emphasized frustration with the lack of implementation of break policies. Female nurses frequently discussed challenges around balancing work demands with personal responsibilities, such as family care, which impacted their ability to rest adequately during shifts. They also noted more about the emotional toll and burnout symptoms.

Unit Differences (A&E vs Medical)

Nurses working in A&E units reported higher stress levels due to patient complexity and unpredictability of cases. They described fewer opportunities for breaks and greater difficulty taking rest because they were often the only RN on the unit during shifts. Nurses in the Medical units acknowledged the challenges of patient care but reported slightly more opportunities for breaks compared to A&E. However, they also noted the workload increased significantly during night shifts.

Experience and Role

More experienced nurses, working 3 years or more, tended to express frustration with systemic issues such as staffing policies and managerial accountability. Less experienced nurses, working less than 3 years, were more likely to discuss immediate physical fatigue and emotional exhaustion, focusing on day-to-day survival rather than broader systemic changes.

Discussion

Summary of Major Findings

This study examined the role of adequate rest in nurse satisfaction, burnout prevention, and physical well-being in medical and emergency units. It uncovered systemic challenges that hinder nurses from obtaining sufficient rest. High patient-to-nurse ratios, staffing shortages, and lack of managerial support were identified as key contributors to fatigue and burnout. Nurses' personal responsibilities, such as caregiving at home, also affected their ability to prioritize rest. These findings show how both institutional and personal factors compromise nurses' well-being and, in turn, patient care.

Interpretation of Demographic Differences

Demographic differences reflect social, cultural, and professional dynamics shaping nurses' experiences. Female nurses often balance work and caregiving roles, heightening stress and burnout risk [23]. A&E nurses reported higher fatigue levels than those in Medical units, due to the unpredictable nature of emergency care. Experienced nurses highlighted systemic issues, while newer nurses focused on the immediate physical and emotional toll, reflecting their frontline pressures [24].

Interpretation of Findings

The study reaffirms the link between rest and well-being. Nurses with more rest reported better physical and mental health, supporting global research on this topic [25]. Challenges at this hospital, such as high workloads and weak managerial support, mirror trends in other resource-limited settings [26]. For example, a Namibian study also found burnout tied to understaffing and lack of rest infrastructure [27]. Nurses at the hospital in Western Jamaica frequently reported physical exhaustion and long-term health concerns, echoing global findings on rest-related health risks, including musculoskeletal pain and emotional exhaustion, key components of burnout [7,25,28].

Relation to Wider Context and Integration With Existing Literature

Jamaica faces a severe brain drain, with 80% of skilled workers emigrating, including health care professionals [29]. Ranking second globally on the brain drain index [30], Jamaica's workforce shortages worsen burnout. Similar trends are noted in Guyana and Trinidad and Tobago [31]. Cultural and economic pressures often lead nurses to work extended hours without adequate compensation or rest. In contrast, high-income countries enforce stricter work hour regulations. At Spanish Town Hospital in Southeast-Central Jamaica, the nurse-patient ratio is 1:10, far above ratios in wealthier nations, contributing to burnout and absenteeism [32-34]. The Maslach Burnout Inventory indicated "very high" burnout among nurses, especially in emotional exhaustion [22,35]. The International Council of Nurses [36] highlights the negative outcomes that occur from high-income countries attempting to address their nursing shortages through "inequitable international recruitment." Through recruiting via migration, it leaves nursing workforces in low- and middle-income countries without adequate care, masks the underlying issues leading to high turnover, and costs low- and middle-income countries lost training expenses after public investment in education.

Nurses struggle to maintain work-life balance in these settings. Overcrowding and understaffing lead to long hours and little time for self-care [37,22]. The State of the World's Nursing Report 2025 [38] illustrated that only 55% of countries had regulations on working hours and conditions, whereas the remaining 45% had partial or no regulations. Care packages for mental well-being of nurses were implemented in 42% of countries, whereas 64% only implemented partial or no care packages. A study in Iceland showed higher satisfaction among nurses working standard hours versus those on overtime [39]. However, extended shifts remain necessary at this hospital in Western Jamaica, negatively affecting health and morale. These findings call for urgent action to support nurses and improve patient care through systemic reform. This is supported by the International Council of Nurses 2025 report [36], which states that solutions such as "ensuring adequate staffing and a balanced skill mix and workforce capacity aligned with patients demands" need to be implemented.

XSL•FO
RenderX

Strengths and Limitations

This study's strength lies in its qualitative design, which captured rich personal narratives often missed in quantitative research [17]. Familiarity between the researcher and some participants may have encouraged openness. However, it may also have introduced bias. The lead researcher's nursing background may have shaped interpretations. Additionally, excluding non-English-speaking nurses, such as Cuban staff [1], limited the diversity of views. With only 12 participants from 2 units, generalizability is limited. Self-reported data also carry risks of under- or over-reporting.

Future Work

Future studies should explore strategies for staff recruitment and retention to reduce burnout. Research is needed on how managerial practices affect rest and well-being. Peer support systems and cultural change around rest and self-care should be evaluated. Post-COVID recovery efforts should prioritize mental health support and enforceable rest policies [40].

Policy and Intervention Recommendations

The hospital should address high nurse-to-patient ratios by increasing staff, ensuring breaks without compromising care. California's Nurse-to-Patient Ratios Law (1:2 in intensive care units; 1:4 in medical-surgical) reduced burnout and improved outcomes [4]. Structured break policies and cross-unit support systems are vital. UK hospitals implementing scheduled breaks reported reduced stress and higher job satisfaction [41]. Australia's cross-unit model ensures continuity of care and relieves pressure during breaks [39,42,43].

Hospital leadership should prioritize nurse well-being. Programs in Australia train managers to promote self-care and regular breaks, leading to greater satisfaction and lower turnover [44]. At Cleveland Clinic in the United States, managerial training on rest and mental health improved morale and retention [45,46]. Wellness programs like Johns Hopkins' Resilience in Stressful Events provide peer support and counseling, significantly reducing burnout and emotional exhaustion among nurses [47].

Conclusion

This study underscores the role of adequate rest in preventing burnout and enhancing job satisfaction among nurses in medical and emergency units. The findings reveal that systemic barriers, such as high workloads, inadequate staffing, and chaotic work environments, significantly hinder nurses' ability to achieve sufficient rest. Nurses in the emergency unit, in particular, face higher stress levels due to the demanding nature of their work, which worsens fatigue and burnout. The lack of localized studies focusing on the physical and mental well-being of Jamaican nurses, particularly in high-pressure emergency units, creates a significant academic gap.

Addressing these issues can enhance the global understanding of burnout in various contexts while providing region-specific strategies to improve nurse retention, job satisfaction, and overall health care quality in Jamaica. A multifaceted approach is required to tackle these challenges, incorporating policy changes, management training, and the creation of supportive work environments. By prioritizing the well-being of nurses through adequate rest, health care institutions can not only improve nurse satisfaction but also ensure better patient care outcomes.

Acknowledgments

The authors are grateful to the director of nursing services at the hospital where the study was conducted for granting permission to carry out the research. We give a special thank you to all the participants for taking part in the study. We are thankful to Imperial College London for their continued academic support and for covering the article processing fee for the publication of this manuscript. The authors used the generative artificial intelligence tool ChatGPT (OpenAI) for editorial assistance in formatting and aligning the manuscript with JMIR submission guidelines. All content was reviewed and finalized by the authors.

Funding

The researchers did not receive funding from any organization to undertake this research. Imperial College London did cover the costs of open access since the study was undertaken as a master's student project. While affiliated with the study, the institution did not influence the study design, data collection, analysis, interpretation of results, or the drafting of the manuscript.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Medical errors occur more frequently in health care than in other industries due to challenges in patient safety education for nurses and students. To address this, it is important to identify the factors and structures underlying clinical errors and apply these insights to educational programs. Medication-related errors are highly preventable with appropriate interventions, highlighting the importance of data-driven safety education. Previous research suggests that unit adaptation, rather than clinical experience alone, plays a critical role in error occurrence. Focusing on "adaptive performance," an underexplored concept in nursing, can help identify new educational strategies and interventions.

Objective: This hypothesis-generating study used Bayesian network modeling to examine how unit experience—and, secondarily, total nursing experience—relates to the structure of medication-related errors, with implications for data-driven patient safety education and nursing student instruction.

Methods: This mixed methods study conducted a qualitative root cause analysis of medication error reports to identify causal factors. Bayesian network modeling, an artificial intelligence–based approach, was used to visualize error-generation flows and compare models based on years of experience within the current unit. Data were obtained from 2023 medication-related error reports submitted by nurses to the Japan Council for Quality Health Care.

Results: Among 119 medication-related incidents, the largest proportion occurred in internal medicine departments (n=47 cases, 39.5%), followed by surgical departments (n=27 cases, 22.7%), the intensive care unit (n=10 cases, 8.4%), and the emergency room (n=7 cases, 5.9%). Most incidents occurred in patient rooms or wards (n=97 cases, 81.5%). Root cause analysis identified 10 types of medication-related events and 23 contributing factors. Cases were categorized into low-, moderate-, and high-adaptation groups based on years of experience in the current unit. In the low-adaptation group (n=33), 69.7% of nurses had ≥5 years of total nursing experience, indicating that the group did not consist solely of novice nurses. The average entropy of incident events across the Bayesian network models ranged from 0.37 to 0.78, suggesting moderate to relatively high uncertainty in the inferred error structures. The moderate- and high-adaptation models exhibited fewer complex error networks, with weaker chains of unsafe conditions or actions than the low-adaptation model. The extensive clinical experience did not always prevent errors; rather, it was often linked to lapses in verification behavior.

Conclusions: Unit adaptation appears to play a critical role in shaping error pathways. Nurses with lower unit adaptation demonstrated more complex error structures, indicating higher vulnerability to incident chains. In contrast, total years of nursing experience did not uniformly reduce risk and may even relate to lapses in verification behaviors.

KEYWORDS

adaptive performance; artificial intelligence; Bayesian network modeling; data-driven education; patient safety

Introduction

Data-driven education is an approach that continuously enhances the quality of instruction and learning by analyzing data generated throughout the educational process [1,2]. In recent years, data-driven education has been increasingly applied to evaluate instructional quality by assessing learning outcomes [3]. However, in nursing education, it is particularly important to utilize real-world data not only for analyzing learner performance but also for informing the design and improvement

XSL•FO
RenderX

of educational systems. Patient safety education is a representative example as it remains an underdeveloped area of curriculum design worldwide, with evident challenges in the early stages of program development. Despite the World Health Organization (WHO)'s concern over the high frequency of medical errors in health care compared with other industries [4], patient safety education remains marginal in nursing curricula, often addressed only informally or as part of broader topics, and research on educational interventions is limited [5,6].

At the core of this issue lies the fundamental nature of health care professionals as practitioners whose work directly influences clinical practice, aligned with indispensable clinical competencies. In response, the American Association of Colleges of Nursing has proposed a framework for competency-based education [7]. Grounded in the principle of "beginning with the end in mind" [8,9], competency-based education is essential for defining learning outcomes and designing effective backward curriculum in patient safety education [10-12]. Nurses are positioned at the frontline of patient care and bear critical responsibility as the final safeguard against medical errors and adverse events. However, in the absence of a well-established and systematic educational framework, they often depend heavily on on-the-job training. This imbalance in educational approaches may ultimately undermine efforts to ensure patient safety.

Among medical errors, medication-related errors are the most preventable and represent an area in which educational interventions can yield substantial improvement [13,14]. A previous study employing Bayesian network modeling (BNM) identified multiple knowledge-, behavior-, and environment-related factors that contribute to medication errors among nurses [15]. These findings indicate that many of these factors can be modified through education, suggesting the potential for significant error reduction. In particular, unfamiliarity with unit-specific tasks and insufficient adaptation to work routines have emerged as key contributors, underscoring the importance of unit adaptation.

Adaptive performance—the ability to respond flexibly to unexpected events and environmental changes [16]—plays a critical role in error occurrence. Medication errors in nursing can be understood as outcomes of performance shaped by fatigue, workload, and environmental conditions [17-19]. Two attribute variables have commonly been used to represent a nurse's experience: total years of nursing experience and years of unit experience. The former is well known from the Benner classification of nursing expertise [20], which applied the 5-stage model and has informed criteria in some clinical ladders [21]. By contrast, unit adaptation has received limited attention in nursing and medical research. Consequently, much of the patient safety literature has focused on novice nurses with limited experience [22-25]. However, understanding the developmental stages and individual differences of adaptive performance is essential for designing effective educational strategies for both nurses and nursing students [26]. Focusing on unit adaptation [16] challenges the view that "inexperience" is defined solely by fewer years of clinical practice and enables a more precise identification of targets for educational interventions.

Accordingly, this hypothesis-generating study used BNM to examine how unit experience—and, secondarily, total nursing experience—relates to the structure of medication-related errors, with implications for data-driven patient safety education and nursing student instruction.

Methods

Study Design

This study used a mixed methods approach consisting of 2 main analytical processes: qualitative factor extraction and relational analysis. First, episodes of medication-related errors involving nurses were qualitatively analyzed using root cause analysis (RCA) to identify the contributing factors [15]. Next, the data were categorized into 3 groups based on years of unit experience: low adaptation (>1 y), moderate adaptation (1 to >3 y), and high adaptation (3 years or more). For each group, BNM was conducted to evaluate the relationships between the factors and compare the structural differences in the flow of medication-related errors.

Data Sources and Data Selection

This study used data from the Medical Error Database published by the Japan Council for Quality Health Care (JCQHC) [27]. The JCQHC undertakes various initiatives, including the collection of medical errors and near-miss cases, to maintain public trust in health care services and improve their quality. The database includes reports from a total of 1899 medical institutions across Japan. The JCQHC requires participating medical institutions to report incidents that fall into the following categories (1–3). (1) Cases in which inappropriate medical care or management was clearly identified and resulted in patient death, permanent physical or psychological impairment, or the need for unexpected or more extensive treatment than anticipated. (2) Cases in which it could not be conclusively determined whether inappropriate medical care or management occurred, but which were otherwise comparable to category (1). (3) Cases other than (1) and (2) that provide useful information for preventing and reducing the recurrence of incidents within health care institutions. The reporting form of the JCQHC requires detailed documentation, including the patient's condition and age group, the working status of the staff involved in the error, the circumstances leading to the incident, and measures for future prevention. From this database, 119 cases were selected for analysis based on the following criteria (): (1) a nurse was involved, (2) the error was medication-related, involving adverse events or equivalent medical errors, and (3) the case included sufficient contextual information to allow for RCA.

Competency and Total Clinical Experience

Although there is no universally accepted definition of nursing competency, it is commonly described as "a core ability required to fulfill nursing responsibilities" [28] or as "the knowledge, behaviors, judgment, skills, values, and attitudes necessary to provide safe, effective, and high-quality care" [29]. These definitions are grounded in experiential learning theory [20] and suggest that competency is a transferable ability developed through the integration of knowledge and skills. In many studies,

XSL•FO
RenderX

total years of clinical experience and length of employment are frequently treated as variables that influence competency development [20,30-32]. In this study, informed by the Benner 5-stage model [20] and its application within clinical ladder systems in the world and Japan [21,33], total years of nursing experience were treated as categorical data (<5 y, 5–10 y, and ≥10 y).

Adaptive Performance and Current Unit Experience

In contrast to competency, performance, particularly work performance, is defined as "behaviors or actions that are relevant to the goals of the organization" [34] and as "scalable actions, behaviors, and outcomes" [35]. Work performance is categorized into 4 domains: task, contextual, counterproductive, and adaptive [36]. Fatigue and burnout are closely associated with work performance among nurses [17], which is a critical element influencing patient safety and holds substantial importance in clinical practice.

Adaptive performance refers to "the extent to which an individual adapts to changes in a work system or work roles" [16]. Although this concept has received limited attention in medical and nursing research, it is theoretically associated with experiential learning [21]. In this study, years of current unit experience were treated as categorical data (low adaptation: <1 y; moderate adaptation: 1 to <3 y; high adaptation: ≥3 y) as a pragmatic proxy for the degree of adaptation to a specific clinical environment, informed by the application of clinical ladder systems in Japan and internationally [21,33]. These 3 groups were intended to correspond to levels of clinical practice and functional independence in the workplace and were operationally defined as follows:

- Low adaptation: the stage of learning all tasks with instructions and follow-ups
- Moderate adaptation: the stage of learning some tasks with instructions and follow-ups while performing other tasks independently
- High adaptation: the stage of performing most tasks independently

Analysis

RCA and Factor Extraction

A total of 119 medical error reports were reviewed to classify events and extract contributing factors. Although the primary coding process was conducted by one researcher, the overall analytical framework was developed through discussions between 2 authors. To minimize subjectivity in factor extraction, a fact-based analytical strategy was adopted. Specifically, contributing factors were strictly derived from observable descriptions in the incident reports rather than from interpretative judgments. The following RCA-guiding questions were applied to ensure systematic extraction: "Why did this event occur?," "What actions or conditions involving the nurse or patient contributed to the event?" "If the event could have been prevented, what actions should the nurse have taken?" In addition, predefined factor definitions were established in advance (Table 1), and contributing factors were extracted as objective facts from the free-text descriptions regarding the event sequence and implemented countermeasures based on consistent criteria. Although some reports included subjective statements—such as the reporter's psychological state or fatigue—these were excluded from the analysis because such descriptions varied among reports and could not ensure objective evaluation. The extracted factors were categorized into 4 groups: attributive, system-related, situational, and knowledge/behavioral. Each factor was labeled within its respective categories. Event classification and factor extraction based on the RCA were reported in our previous study [15], and their validity was confirmed through consistency with prior research [37].

Table . Explanations of nodes.

Node	Explanation
Event	
Wrong dose	Administered the wrong dose of medication
Wrong patient	Administered medicine to wrong patient
Improper mixing	Performed improper mixing
Wrong or unnecessary administration	Administered a different medication to the one that should have been administered or administered a medication unnecessarily
Overlooking contraindication	Missed contraindicated medication
Accidental ingestion/ overdose	Patient accidentally ingested or overdosed
Incorrect storage	Stored medicine in an incorrect storage method
Wrong timing	Administered medicine at the wrong time
Default of medication discontinue	Failed to discontinue medicine
Wrong route	Administered medicine by the wrong route
Attributional factors	Factors related to the attributes of nurses who made errors
Year as registered nurse	Divided into 5 years as registered nurse
<5	Including novice, advanced beginner, and competent nurse
5 - 9	Including proficient nurse
≥10	Including expert nurse
Year as current unit	Divided into 3 stages of learning the tasks of a typical Japanese hospital unit
<1	The stage of learning all tasks with instructions and follow-ups
1 - 3	The stage of learning some tasks with instructions and follow-ups, but performing some tasks independently
>3	The stage of performing most tasks independently
System factor	Factors related to the organization's systems, such as electronic medical records and educational systems
Failure to detect by the electronic system	Not equipped with the ability to detect on electronic medical record system
Conditional factors	Factors related to conditions surrounding nurses. For example, the time of day, the type of work, and other conditions when errors had occurred
Weekday/holiday	Occurred during weekday or holiday
Work time	Work time was divided into 3 parts according to the patient's life and the nurse's work behavior
9 AM-4 PM	
4 PM-9 PM	
9 PM-9 AM	
Day shift/night shift	Occurred during day shift or night shift
Patients' age (y)	Age of patients associated with errors
<20	
20 - 59	
≥60	
Time pressure	Time pressure was present due to sudden emergencies or multiple tasks of the patient
Sudden change in patients' schedule	There was a sudden change in schedule for examination or treatment
Failure of doctor's orders	There was a failure of doctor's orders.
Patients who do not follow instructions	Patient did not follow the instructions of health care professionals

XSL•FO
RenderX

Node	Explanation
Knowledge and behavioral factors	Factors related to nurses' knowledge state and behavior.
Failure to confirm the 5 rights	Had not checked the 5 rights
Assumptions and forgetfulness	Assumed or forgot instructions and orders
Invalid double check	Nurses double-checking each other was invalid
Improper use of instruments and equipment	The use of instruments and equipment induced errors
Insufficient knowledge of medications	Did not have sufficient knowledge
Unfamiliarity with operations of medications	Did not know how to properly handle medications due to unfamiliarity
Failure of information communication	Discrepancies in communication when conveying information
Improper handling of medications	Handled medicine in the wrong way
Failure of monitoring	Monitoring was a possibly avoidable error
Task interruption	Task interrupted when error occurs
Non-reconfirming of inappropriate doctor's orders	Did not check again even though nurse felt the doctor's instructions were inappropriate
Lack of explanation to patients	Not enough explanation about medication to the patient
Miscalculation	Miscalculated appropriate medication dosage

Bayesian Network Modeling

BNM is an artificial intelligence (AI)–based probabilistic approach that represents qualitative dependencies among multiple variables through a graphical structure and expresses quantitative relationships using conditional probabilities [15]. In this study, each event and contributing factor was represented as a "node," and causal or temporal relationships were indicated by "edges" connecting these nodes. The analysis was performed using BAYOLINK version 7.0.1 (NTT DATA Mathematical Systems), employing a greedy algorithm with an Akaike information criterion threshold of 0.02 [38]. We used this algorithm and criterion to avoid overlooking even weak associations between incidents and contributing factors, as well as relationships among the factors themselves, because this study was positioned as a hypothesis-generating investigation. While previous patient safety research has primarily relied on qualitative analyses based on individual incident case reviews or simple descriptive surveys, this study aims to explore hypotheses regarding common structural patterns underlying specific incident occurrences and the characteristics of contributing factors derived directly from the data.

Model construction combined algorithmic computation with expert judgment [15]. A major advantage of this method is its ability to infer potential causal relationships from relatively small datasets based on information criteria. During the process of model development, whitelist and blacklist constraints were applied to refine the network structure. No whitelist was specified, and the initial blacklist included attributive and system-related factors, which were conceptually treated as root-level nodes without parent relationships. This classification was informed by human factors–based frameworks [37,39]. These constraints were iteratively updated to remove irrelevant links and maintain logical consistency in the causal and temporal relationships. Final models were constructed for each adaptation group.

Unit experience was classified into 3 adaptation levels based on the general clinical ladder for nurses in Japan: low adaptation (<1 y), moderate adaptation (≥1 and <3 y), and high adaptation (≥3 y) [15]. The low-adaptation group was defined as the stage in which nurses performed all tasks under instruction and supervision. The moderate-adaptation group was defined as the stage in which nurses performed some tasks independently, while still requiring instruction and follow-up for others. The high-adaptation group was defined as the stage in which nurses performed most tasks independently. Consistent with the secondary objective of this study, when the node "Year as registered nurse" (categorical variable: <5 y, 5–9 y, and ≥10 y) was included in a model, the category associated with medical error occurrence was identified. The structural differences between the 3 models were evaluated based on the number of layers and the number and characteristics of factors not directly associated with adverse events or equivalent medical errors.

The average entropy was calculated as an indicator of uncertainty in BNM. When the child node is a binary variable, the average entropy ranges from 0 to 1.0, where lower values indicate lower uncertainty. For example, when the cross-tabulation between a parent node A (binary) and a child node B (binary) is completely uniform, the uncertainty reaches its maximum and the value becomes 1.0. A smaller value of the average entropy indicates that the state of the child node can be more easily determined, given the condition of the parent node. Although there is no universally established threshold for interpreting the magnitude of average entropy, in this study, the average entropy was calculated only for binary nodes, and therefore, the values were restricted to the range of 0 to 1.0. Accordingly, the model was evaluated comparatively within this range.

Ethical Considerations

This study used data from the anonymized and publicly available database of the JCQHC [26]. Therefore, it did not violate any

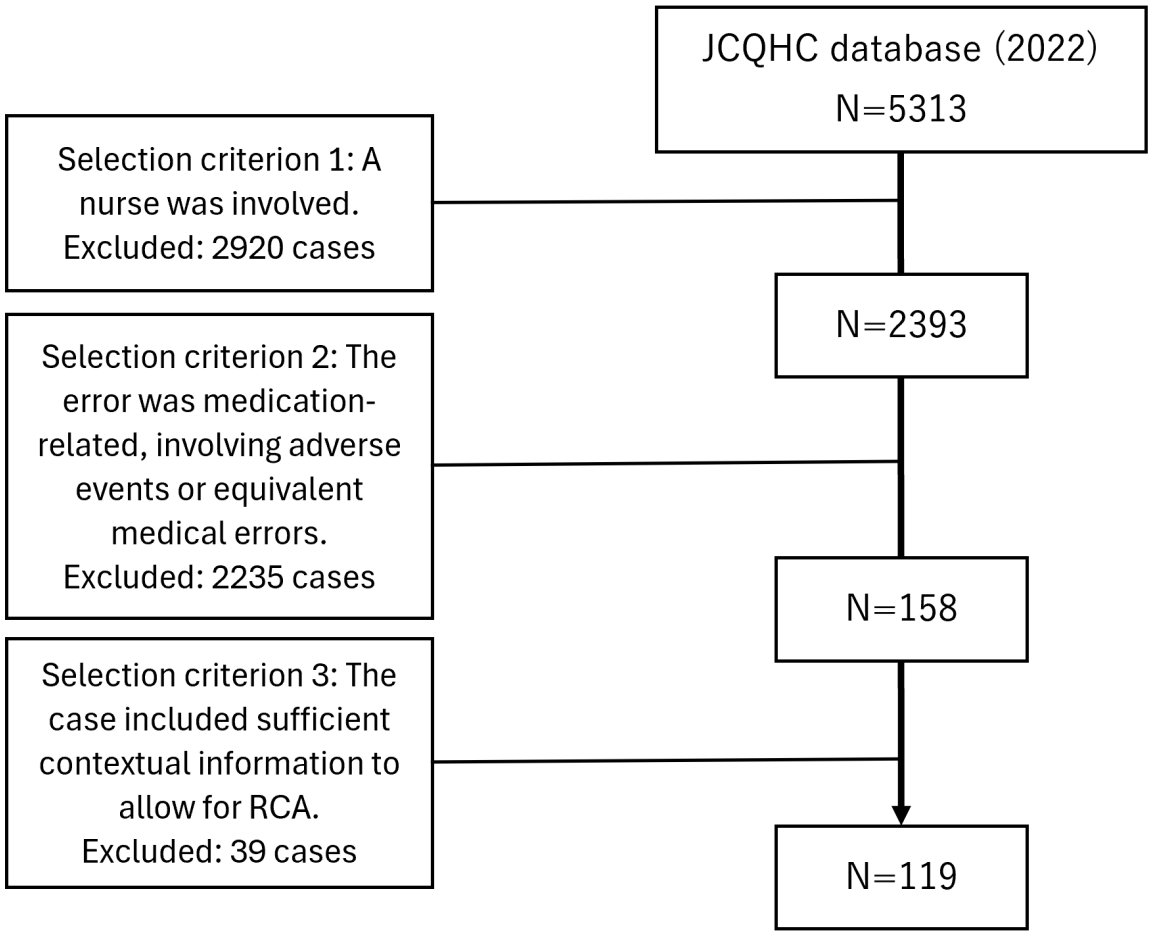
privacy policies and did not fall under the scope of an ethics review.

Results



Descriptive Statistics

The distribution of the 119 incidents by clinical department was as follows. A total of 27 (22.7%) incidents occurred in surgical departments: neurosurgery (n=7 cases, 5.9%), orthopedic surgery (n=5 cases, 4.2%), gastrointestinal surgery (n=3 cases, 2.5%), cardiovascular surgery (n=1 case, 0.8%), plastic surgery (n=1 case, 0.8%), and oral and maxillofacial surgery (n=1 case, 0.8%). An additional 11 (9.2%) incidents were categorized as "other surgical departments," referring to cases documented only as "surgery" or from mixed surgical wards (Figure 1).

A total of 47 (39.5%) incidents occurred in internal medicine departments: cardiology (n=7, 5.9%), hematology (n=6, 5.0%), gastroenterology (n=5, 4.2%), pulmonology (n=3, 2.5%), otorhinolaryngology (n=3, 2.5%), metabolism/endocrinology (n=3, 2.5%), neurology (n=2, 1.7%), dermatology (n=1, 0.8%), rheumatology (n=1, 0.8%), oncology (n=1, 0.8%), and general internal medicine (n=1, 0.8%). Another 14 (11.8%) incidents were categorized as "other internal medicine departments," referring to cases recorded only as "internal medicine" or from mixed internal medicine wards.

In addition, 10 (8.4%) incidents occurred in the intensive care unit, 7 (5.9%) in the emergency room, and 4 (3.4%) in the neonatal intensive care unit. Other clinical areas included obstetrics and gynecology (11 incidents), pediatrics (9 incidents), psychiatry (1 incident), and palliative care (1 incident).

Figure 1. Data selection process. JCQHC: Japan Council for Quality Health Care; RCA: root cause analysis.

The distribution of incident locations was as follows. Patient rooms and wards accounted for the majority of cases (n=97 incidents, 81.5%), followed by outpatient clinics (n=12, 10.1%). Other locations were operating rooms (n=5, 4.2%), radiology examination rooms (n=3, 2.5%), dialysis units (n=1, 0.8%), cardiac catheterization laboratories (n=1, 0.8%), and patients' homes (n=1, 0.8%).

Medication-related errors were classified into 10 event types, and 23 contributing factors were extracted (Table 1). Descriptive statistics by the unit experience group are summarized in Table 2. In the adaptation group (n=33), defined as nurses with less than 1 year of current unit experience, 8 (24.2%) had 5 to 9 years' experience as registered nurses and 15 (45.5%) had ≥10 years. These findings indicated that this group was not composed solely of nurses with limited clinical experience.

Comparison of Models by Adaptation Levels

The BNM results for the 3 adaptation groups (low, moderate, and high) are presented in Multimedia Appendices 1-3, and the comparison of their structural characteristics is summarized in Table 3. In each model, the incident event was positioned at the lowest level, while the most distal contributing factors were represented as level 1. The average entropy of the incident events ranged from 0.44 to 0.76 in the low-adaptation model, from 0.55 to 0.78 in the moderate-adaptation model, and from 0.37 to 0.75 in the high-adaptation model. In the low-adaptation model (Multimedia Appendix 1), the structure consisted of up to 5 layers. Four nodes were excluded from the model: 2 event nodes ("Incorrect storage" and "Wrong route") and 2 factor nodes ("Patients who do not follow instructions" and "Miscalculation"). Three factor nodes were included in the model but were not connected to any event nodes: "Lack of explanation to patients," "Failure of information communication," and "Time pressure."

XSL•FO
RenderX

Table . Comparison of model structures.

Comparison criteria	Low-adaptation model (n=33)	Moderate-adaptation model (n=36)	High-adaptation model (n=50)
Maximum number of layers	5	4	4
Number of events not included in the model	2	2	1
Node	Incorrect storage and wrong route	Wrong timing and wrong route	Wrong timing
Number of factors not included in the model	2	2	5
Node	Patients who do not follow instructions, miscalculation	Year as registered nurse, task interruption	Time pressure, assumptions and forgetfulness, failure of monitoring, lack of explanation to patients, miscalculation
Number of factors not related to events	3	7	5
Node	Time pressure, failure of information communication, and lack of explanation to patients	Failure to detect by the electronic system, assumptions and forgetfulness, invalid double check, failure of information communication, non-reconfirming of inappropriate doctor's orders, lack of explanation to patients, miscalculation	Work time, failure of doctor's orders, insufficient knowledge of medications, failure of information communication, non-reconfirming of inappropriate doctor's orders

The moderate-adaptation model (Multimedia Appendix 2) had a maximum of 4 layers, with 4 nodes excluded from the model: 2 event nodes ("Wrong timing" and "Wrong route") and 2 factor nodes ("Years as registered nurse" and "Task interruption"). Seven factor nodes were included in the model but were not connected to any event nodes: "Lack of explanation to patients," "Miscalculation," "Failure of information communication," "Failure to detect by the electronic system," "Invalid double check," "Assumptions and forgetfulness," and "Non-reconfirming of inappropriate doctor's orders."

In the high-adaptation model (Multimedia Appendix 3), the structure consisted of up to 4 layers. Six nodes were excluded from the model: one event node ("Wrong timing") and 5 factor nodes ("Time pressure," "Assumptions and forgetfulness," "Miscalculation," "Lack of explanation to patients," and "Failure of monitoring"). Five factor nodes were included in the model but were not connected to any event nodes: "Insufficient knowledge of medications," "Failure of information communication," "Work time," "Failure of doctor's orders," and "Non-reconfirming of inappropriate doctor's orders."

The node "Years as registered nurse" was included in both the low- and high-adaptation models (Multimedia Appendices 1 and 3). In the low-adaptation model, all categories except nurses with 5 to 9 years were positively associated with "Failure to confirm the five rights," and nurses with ≥10 years were positively associated with "Wrong or unnecessary administration." In the high-adaptation model, nurses with 5 to 9 years were positively associated with "Failure of information communication" and "Invalid double check," whereas all categories except nurses with less than 5 years were positively associated with "Wrong dose."

Discussion

Key Results

This hypothesis-generating study examined whether years of experience of nurses in their current unit, used as an indicator of unit adaptation, might be related to medication-related errors. While prior qualitative studies have highlighted the importance of adaptation [40], our mixed methods approach using an AI-based BNM suggests the potential for a more objective and quantitative assessment.

Incident causation inherently involves uncertainty because incidents arise from complex interactions among contextual and behavioral factors rather than predetermined outcomes. The moderate to slightly high entropy values observed in this study reflect this uncertainty and should be interpreted as relative indicators. Future studies with larger samples and additional variables, such as work environment factors, may help improve model stability and reliability.

BNM integrates expert judgment while reducing subjectivity through probabilistic modeling, differing from approaches that rely solely on RCA. Consistent with the Reason Swiss Cheese Model [41], our analysis visualized a multilayered structure of medication-related errors. Especially in the low-adaptation model, unsafe conditions and behaviors appeared to precede subsequent unsafe actions, suggesting a potential chain of events. The findings provide preliminary insights into how unit adaptation may influence error structures although this study is limited by its sample size and the interpretive constraints inherent to probabilistic modeling.

Objectivity of RCA, Conceptual Validity, Causality, and Robustness of Hierarchical Structure Models

International studies on medication incidents have mainly reported that wrong dose errors account for a large proportion

XSL•FO
RenderX

of events and that adherence to the "five rights" is a critical factor [37]. The descriptive statistics of incident events and contributing factors in the present study were generally consistent with these prior findings. Although the existing literature is limited, no notable bias was observed in the dataset used in this study.

With respect to RCA, factor extraction was deliberately restricted to elements that could be objectively derived from narrative descriptions; subjective elements prone to inconsistent reporting—such as psychological states and perceptions—were excluded. Furthermore, each incident event and its contributing factors were coded using predefined operational definitions to safeguard objectivity in the extraction process.

For the BNM, relationships among factors were specified with reference to human factors theory, drawing on frameworks [37,39]. These specifications informed the blacklist constraints, thereby supporting the conceptual validity of the resulting network structures.

Regarding the hierarchical structure models, the intent was not to establish definitive causal relationships but to conduct a hypothesis-generating exploration. All nurse knowledge and behavioral factors identified through RCA were treated as potential contributors, and the BNM was used to examine shared structural patterns and differences by unit experience. A greedy algorithm guided by the Akaike information criterion was selected to detect weak associations and latent risks without excluding relevant links, allowing modeling even with a relatively small sample size. However, the limited sample size constrains model stability and robustness, and the results should be interpreted as provisional hypotheses rather than confirmed evidence. The models do not determine causal relationships among factors or between factors and incidents. Future studies should increase the sample size and conduct cross-regional analyses to empirically test the hypotheses generated here.

Effect of Adaptation on Patient Safety

As the concept of adaptive performance suggests, nurses' adaptation to their unit is expected to enhance their problem-solving abilities, predictive practice skills, behavioral flexibility, and adjustment to the organizational culture and physical environment in highly uncertain clinical settings [19]. The findings of this study appear to be consistent with these expectations.

As shown in Table 2, incident-related factors did not decline sharply with increasing adaptation. However, the comparison of the 3 model structures (Multimedia Appendices 1-3) suggests that the overall number of layers leading to incident occurrence becomes fewer as adaptation increases. One possible interpretation is that the low-adaptation group shares more homogeneous incident pathways, making certain unsafe conditions more likely to trigger errors. This trend underscores the importance of population-level patient safety education that supports early adaptation among novice and newcomer nurses.

Table 3 further shows that several factors—such as "Work time," "Failure of information communication," and "Non-reconfirming of inappropriate doctor's orders"—were not directly connected to incidents in the high- and moderate-adaptation models. Other factors, including "Time pressure," "Insufficient knowledge of medications," and "Lack of explanation to patients," were not included in the models at all. These patterns suggest two potential effects of unit adaptation: (1) improved adaptation to work processes, such as anticipatory multitasking, increased psychological resilience, acquisition of unit-specific pharmacological knowledge, and the ability to provide appropriate patient explanations [42]; and (2) enhanced adaptation to organizational culture, including smoother communication with colleagues and other health care professionals [43,44]. These interpretations remain tentative, and larger samples are needed to assess the stability and robustness of these structural differences.

Across all models, a consistent structure emerged involving "Wrong patient" and its associated factors—"Failure to confirm the 5 rights" and "Improper use of instruments and equipment." Addressing these issues will likely require approaches beyond those focused solely on promoting unit adaptation.

Considerations Regarding the Impact of Extensive Clinical Experience on Patient Safety

Previous studies on clinical experiences have primarily focused on patient safety measures for novice nurses with limited experience [22-25]. However, the inclusion of the node "Years as registered nurse" in both the low- and high-adaptation models indicated that extensive clinical experiences did not necessarily contribute to reducing errors. Instead, positive associations were observed with behaviors such as "Failure to confirm the five rights" and "Invalid double check," suggesting lapses in verification behaviors.

One possible explanation is the emergence of inappropriate adaptation, in which safety behaviors become ritualized and lose their intended effectiveness. Another possibility is the presence of a cognitive bias whereby experienced nurses are assumed by other staff to be less likely to make errors, leading to the invalidation of double-checking procedures [45]. Although the potential negative effects of extensive clinical experiences have rarely been considered, and the present findings do not allow us to conclude a causal relationship between greater years of experience and errors in verification behaviors, the consistent adherence to safety-verification practices should apply to all nurses, regardless of their level of experience.

Practical Implications

The most significant contribution of this study lies in suggesting that, while previous research has emphasized the lack of clinical experiences among novice nurses as a major issue for patient safety [22-25], our analysis of real-world data indicates that challenges in adapting to clinical units may also underlie this issue. This represents a novel application of AI in nursing education [46]. These findings underscore the potential importance of supporting nurses' adaptation to their assigned units—not only for newly graduated nurses but also for those who have recently transferred to new settings. Educational approaches that emphasize adaptation may also play a meaningful role in the training of other health care professionals. Further hypothesis-testing research will be required.

XSL•FO
RenderX

As possible practical interventions, intensive orientation programs focusing on unit-specific workflows during the initial assignment phase, along with educational initiatives aimed at improving medication knowledge and fostering safe practices, may be effective. In the field of safety behavior training, virtual reality programs have been developed and applied to surgical education [47]. Following this example, scenario-based simulation training can be designed using the results of the present models to reproduce situations in which unsafe nursing behaviors are likely to cascade.

Furthermore, the models presented in this study can be used as feedback tools for safety management and education, reflecting individual differences in clinical experiences and adaptation levels. Although adverse events and medical errors are often influenced by multiple latent factors [37], postevent instructions tend to focus primarily on direct causes due to hindsight bias. The multilayered structures revealed in the current models may help overcome this bias by encouraging more comprehensive and proactive safety-management strategies.

Limitations and Future Work

We conducted RCA based on narrative descriptions of reported medical errors. Therefore, situations or latent factors unrecognized by reporting nurses may not have been captured in the analysis. In particular, nurses with extensive clinical experiences often care for critically ill patients or manage heavier workloads, which may serve as underlying factors contributing to counterproductive behaviors, such as task shortcuts or neglect of verification behaviors [48]. However, this limitation is not unique to this study but rather reflects a structural issue common to existing incident reporting systems worldwide. Indeed, prior studies on nurse fatigue risk management have rarely incorporated variables such as patient load and workload in a systematic manner. In addition, even in routine clinical practice, systems for consistently recording indicators such as the number of patients per nurse or patient acuity for the purpose of workload analysis are often lacking. If quantitative approaches to analyzing incident reports—such as those explored in our study—become more established, they may contribute to future international discussions on revising reporting standards.

Another limitation concerns the balance between global and local optimization in the analysis; that is, the extent to which institutional characteristics are incorporated depends on the research purpose and may affect the generalizability of the results [2]. In this study, organizational factors specific to individual institutions could not be extracted from the report narratives. Future research should compare data across institutions and design unit-specific or institution-specific training programs, followed by an evaluation of their effectiveness and acceptability [49].

The findings from the hierarchical network models in this study should be regarded as exploratory and hypothesis-generating rather than definitive. Future work is needed to expand the sample and to evaluate the stability and robustness of the model structures through random-sampling approaches, such as analyzing pre- and post-COVID-19 datasets [50] and employing bootstrap methods [51].

The variable “Years of nursing experience” spans a broad continuous range, so it was converted into categorical data using 5-year intervals, following classifications commonly used in clinical ladder systems [21,33]. This categorization, however, is not definitive. Greater experiences may also reflect age-related factors, and although declines in work ability with age are well recognized in occupational health [52], they have rarely been examined in medical or nursing contexts. Further research is needed to clarify how nursing experience relates to work performance and to determine more appropriate ways of grouping experience levels.

Conclusions

This hypothesis-generating study applied an AI-based BNM to examine structural patterns underlying medication-related errors, demonstrating the value of a quantitative, probabilistic approach that goes beyond the traditional RCA. The use of BNM represents a novel methodological contribution in patient safety research by combining expert judgment with reduced subjectivity and enabling structural comparison across experience groups. The findings suggest that unit adaptation plays an important role in shaping error pathways: low-adaptation nurses showed more layered and homogeneous structures leading to unsafe actions, indicating a higher vulnerability to incident chains. In contrast, total years of nursing experience did not uniformly reduce risk and may even relate to lapses in verification behaviors. Together, these results highlight the need to support adaptation not only among new graduates but also among nurses transitioning to new units, while reinforcing verification practices across all experience levels. Further empirical studies are needed to validate these preliminary hypotheses.

Abstract

Background: Understanding current nursing workflows is essential to informing future workforce redesign strategies, including virtual nursing roles. However, granular insights into current nursing workflows over a 24-hour period and across different staff grades are lacking.

Objective: This study aimed to (1) quantify how registered and enrolled nurses in the general acute medicine wards distribute their time across direct and indirect care tasks over a 24-hour period, (2) identify multitasking burdens and temporal distributions, and (3) identify opportunities for the development of a virtual nursing role.

Methods: Using time-and-motion methodology, we observed registered and enrolled nurses in 3 general medicine wards over a 24-hour period between April 2024 and June 2024. We observed 3 task categories (administrative, communication, and bedside tasks), with multiple individual tasks monitored under each category. Multitasking (ie, the occurrence of 2 or more tasks concurrently) was also tracked. The checklist was piloted and refined before data collection.

Results: We observed a total of 48 nursing shifts. During the daytime, registered nurses spent 70% (587/834 min) of their time on indirect care tasks compared with 54% (412/764 min) of the time for enrolled nurses. At night, the proportion of time spent on indirect care tasks decreased to 58% (410/705 min) for registered nurses and 39% (274/711 min) for enrolled nurses. During a 24-hour period, registered nurses spent 209 (SD 51.8) minutes multitasking in the day and 117 (SD 41.0) minutes at night, whereas enrolled nurses spent 152 (SD 54.7) minutes multitasking in the day and 110 (SD 75.9) minutes at night.

Conclusions: These findings highlight opportunities for virtual nursing roles, which, if thoughtfully designed, may help redistribute indirect care tasks, reduce multitasking burden, and enhance overall efficiency without compromising care quality.

time and motion; nursing workflows; multitasking; inpatient; virtual nursing

Introduction

Background

Health systems are facing a myriad of workforce challenges. Populations are aging, increasing the demand for care and the complexity of the care required [1]. Simultaneously, the workforce is shrinking; by 2030, the World Health Organization projects an estimated shortfall of 11 million health workers [2]. Furthermore, high-income nations find it increasingly challenging to recruit and retain home talent, relying on foreign workers to fill staffing gaps [3]. Challenges in recruitment and retention are further exacerbated by the increasing levels of staff dissatisfaction and burnout reported in recent years [4]. Collectively, these challenges raise significant questions about the sustainability of health care if no change occurs.

To address workforce challenges, there is an urgent need for role redesign and the careful application of technology to streamline processes and automate tasks. At Alexandra Hospital

XSL•FO
RenderX

in Singapore, a new approach is being pioneered—the integration of a virtual workforce enabled through technology. Supported by the Ministry of Health, the hospital is investing in the development of remote or "virtual" nurses. In this context, virtual nursing refers to an emerging model of practice in which qualified nurses provide support to clinical team members remotely through digital technologies, thereby complementing bedside nursing. For example, virtual nurses may remotely monitor vital signs and fall risk, act as virtual discharge coordinators, participate in rounding through teleconsultation, or provide remote patient and caregiver education and staff supervision [5-8]. Additionally, the introduction of new virtual roles will provide more flexible work options such as working from home, which can support staff retention efforts [9]. Thus, virtual nursing is a promising model for workforce redesign.

To develop the virtual nursing workforce, understanding the status quo is important. Nurses are responsible for a range of direct (ie, involving direct interaction with patients) and indirect (ie, performed away from the patient) patient care tasks, including administering medication, monitoring patient conditions, coordinating with other health care providers, and managing administrative duties [10]. It is also well known that nurses handle diverse and often conflicting tasks, often leading to overwork and suboptimal practice [11] (eg, the duality of direct and indirect patient care tasks competing for attention). Furthermore, it has been widely reported that nurses frequently multitask (ie, perform multiple tasks simultaneously) throughout the day, which can create inefficiencies, increase the risk of errors, and reduce overall quality of care [12].

At the same time, nursing practice is fundamentally grounded in caring science, where the therapeutic nurse-patient relationship and presence are central to promoting healing and well-being [13]. However, growing administrative burden, competing indirect care demands, and multitasking can displace the relational aspects of care that form the essence of nursing. Therefore, understanding how nurses currently spend their time is essential not only for efficiency but to safeguard opportunities for caring practices. Role redesign—including virtual nursing—must be guided by the principle that technology should preserve and enhance nurses' ability to deliver person-centered, relational care.

Despite this, much of the existing evidence base is qualitative, and there remains a gap in quantitative measurement. Where quantitative data exist, there is limited data capture on nighttime activities, the occurrence and patterns of multitasking over a 24-hour period, and the tasks undertaken by different staff grades (eg, registered nurses, who are qualified to dispense medications and instruct junior nurses, and enrolled nurses, who primarily handle patient care, such as bathing, feeding, and toileting) [10,11,14,15]. This study addresses these gaps by systematically mapping real-world nursing activity over a 24-hour cycle, examining the distribution of direct and indirect care tasks, identifying when multitasking occurs, and comparing activity patterns across staff grades. By doing so, this study provides empirical evidence to inform the design, timing, and scope of virtual nursing roles, identifying activities suitable for remote support without compromising patient-facing care.

Aims

Our aims were as follows:

1. To quantify how registered and enrolled nurses in the general acute medicine wards distribute their time across direct and indirect care tasks over a 24-hour period
2. To identify multitasking burdens and temporal distributions
3. To identify opportunities for the development of a virtual nursing role

Methods

Overview

We used time-and-motion methodology to map and quantify the tasks and time spent on direct and indirect patient care in an inpatient setting. In brief, time and motion involves a period of continuous observation and timing of activities. This study is reported according to the Suggested Time and Motion Procedures checklist [16].

Participants

This study was conducted at Alexandra Hospital in 3 general acute medicine wards. Ward sizes range from 19 to 33 beds, and each has several isolation beds where additional infection control measures are in place (eg, methicillin-resistant *Staphylococcus aureus* precautions). The typical nurse-to-patient ratio is 1 nurse for every 4 or 5 patients, with nurses opting for various full-day (12-hour) shifts or partial day shifts. A typical ward comprises a team of registered nurses (who are qualified to dispense medications and instruct junior nurses), enrolled nurses (who primarily handle patient care, such as bathing, feeding, and toileting), and a nurse manager who oversees ward operations. Each nurse has access to the electronic medical record (EMR) system through desktop computers or mobile phones (ie, Epic Rover).

As the roles of registered nurses and enrolled nurses are distinct, we observed both profiles through convenience sampling during a 3-month period. Inclusion criteria were being a full-time staff member and having worked on the wards for at least 6 months. Exclusion criteria were basic care assistants, part-time workers, or those with less than 6 months of experience on the wards. The month before data collection commenced, briefing sessions were held with the nurse managers to introduce the research project and seek their approval. Observers (health service research staff) had no direct relationship with the nursing staff being observed.

Data Collection

The initial checklist of observation items was developed through consultation with the ward managers and comprised 3 overarching domains (administrative, communication, and bedside tasks), 8 task subcategories (activities of daily care, patient communication, clinical care, administrative tasks, staff communication, staff education, ward observation, and break time), and 27 individual task codes, mapped in Table 1. The checklist was piloted and refined during observations between November 29, 2023, and December 8, 2023, before the actual data collection commenced. A second pilot was conducted from April 9 to 12, 2024, to standardize the observation process and

XSL•FO
RenderX

train the 10 observers. Tasks were observed and tracked concurrently to capture periods of multitasking (ie, when 2 or more tasks were performed at the same time). For example, a communication task could be timed at the same time as a bedside care task. In our study, transition periods (short intervals between the end of one task and the start of another) were recorded as part of the subsequent task whenever the transition was functionally inseparable from task initiation (eg, walking from a workstation to a patient's bedside to begin care).

Data collection consisted of continuous nurse observation over 1 complete work shift (8:30 AM-8 PM or 8 PM-8:30 AM). Observations were conducted between April 15, 2024, and June 24, 2024. A roster was created in Python (version 3.8; Python Software Foundation) randomly allocating observers across different days of the week and weekend slots across the 3 wards. We used the Time Capture Tool TimeCaT on an iPad (Apple Inc) to track activities. TimeCaT is a validated tool frequently used in observations of health care processes [17]. Tasks are entered into the app a priori, and observers select the appropriate task as it occurs, activating a timer. Observers can also add notes to specific data points. During data collection, we also captured bed occupancy, the number of patients discharged, and the number of bed days.

Table . Direct and indirect care tasks, subcategories, and individual task codes.

Task categories and subcategories	Task codes
Direct care tasks	
Supporting activities of daily living	• Ambulation • Bathing • Changing bedding • Diapering or assisting with toileting • Assisting with food and drink
Patient communication	• Nurse to patient • Meal ordering • Attending patients' call bell
Clinical care	• Vital sign taking • Laboratory samples (collection and sending) • Other assessments and procedures • Medication handling • Patient comfort • Patient transfer (diagnostics) • Waste disposal (clinical and nonclinical waste)
Indirect care tasks	
Administrative	• Electronic medical record entry • Record viewing (no data entry) • Nonclinical administrative tasks • Discharge or admission
Staff communication	• In-person staff member to staff member • Remote staff member to staff member • Remote staff member to caregiver • Handover • Team meetings
Staff education	• Staff education
Ward observation	• Observing patients
Break time	• Break

Ethical Considerations

This study was reviewed and approved by the National University of Singapore Ethical Review Board (NUS-IRB-2023-327). A waiver for consent was obtained from the National University of Singapore Institutional Review Board. Data were anonymous and analyzed at the aggregate level. Participants were not individually compensated.

Data Analysis

Before analysis, each observation data file was cleaned. TimeCaT includes a note function that allows observers to comment on specific data points. Each note was reviewed, and revisions were made to the data if required (eg, removal of tasks that were erroneously timed or relabeling of incorrect observations). We then mapped the observed tasks to direct and indirect care tasks, creating subcategories within each domain. Direct care tasks involved direct interaction with the patient

XSL•FO
RenderX

(eg, bathing and procedures), and indirect care tasks were those that were performed away from the patient (eg, documentation and staff communication) but on behalf of the patient (Table 1).

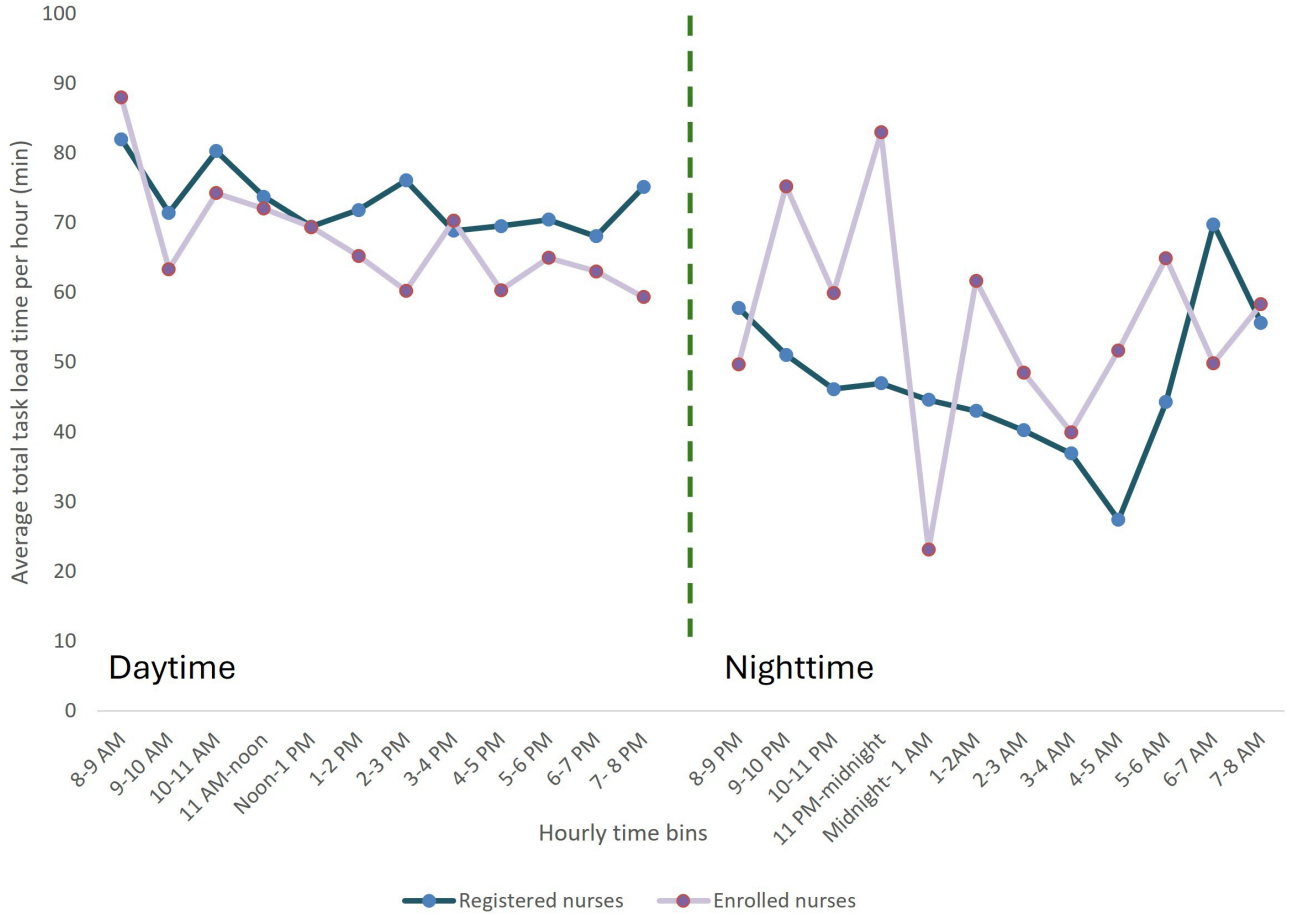
Time-and-motion data were analyzed in multiple steps. To calculate the average time spent on each task, we summed the total time spent on each task across all observations, including instances in which the task was not performed (ie, zero time), and divided it by the total number of observations. This produced the average task load time for a typical day or night shift. We then calculated the total task load time for a shift by summing all average task times and used this value to determine the proportion of time spent on each task as a fraction of the total task load time. To analyze the data by hour, each observed task was assigned to a 1-hour "time bin." For example, a task performed from 9:01 AM to 9:20 AM was categorized under the 9 AM to 10 AM time bin and recorded as 19 minutes. If a task spanned multiple time bins, its duration was divided accordingly. This approach enabled accurate tracking of task distribution across the 24-hour period. We also measured multitasking by calculating the total time during which 2 or more tasks were performed simultaneously (eg, communication and administrative tasks). Periods of no activity were excluded from the analysis. All data processing and analyses were conducted using Python (version 3.8) and Stata (version 19; StataCorp LLC).

Validity and Reliability

The observation checklist was tested and optimized over 6 separate pilot observations (a total of 17.5 hours) between November 29, 2023, and December 8, 2023. Prior to the actual data collection, a training session was conducted (April 8, 2024) to introduce the team of observers to the process and address any initial questions. A set of training observations was then conducted in pairs from April 9 to 12, 2024, to familiarize the observers with the process, standardize coding of observed tasks, and ensure that the checklist was complete. The team met 4 times during this period to discuss coding alignment and resolve any questions. Interrater agreement was assessed during the pilot phase of the study [18]. As tasks across the 3 domains (administrative, communication, and bedside) could occur concurrently, the Cohen κ statistic and percentage of agreement were calculated separately for each domain. For each observer pair, a 30-minute observation period was analyzed. The observational data were divided into 30-second intervals, and agreement between coders was assessed based on the task assigned to each interval. κ values ranged from 0.62 to 0.69, indicating substantial agreement, whereas the percentage of agreement ranged from 78% to 84%, reflecting good consistency between coders. Formal data collection commenced on April 15, 2024.

Results

Overview



During the study period, we observed 48 shifts, including a total of 30 nurses during the day (8:30 AM-8 PM; n=22, 73.3% registered nurses and n=8, 26.7% enrolled nurses) and 18 nurses at night (8 PM-8:30 AM; n=14, 77.8% registered nurses and n=4, 22.2% enrolled nurses). The total active task observation time for registered nurses was 164 hours and 29 minutes, and for enrolled nurses, it was 47 hours and 22 minutes. During the observation period, bed occupancy ranged from 71% to 90%, and 1044 patients were discharged from the wards, representing 5559 bed days.

Task Load Over a 24-Hour Period

Task load varied over the course of 24 hours, with higher variability at night—particularly for enrolled nurses (Figure 1). During the day, the highest peak in task load for registered and enrolled nurses was between 8 AM and 9 AM, whereas the lowest task load was between 6 PM and 7 PM for registered nurses and between 7 PM and 8 PM for enrolled nurses. In the night shift, the highest task load peak was between 6 AM and 7 AM for registered nurses and between 11 PM and midnight for enrolled nurses. Conversely, the lowest task load was observed from 4 AM to 5 AM for registered nurses and midnight to 1 AM for enrolled nurses.

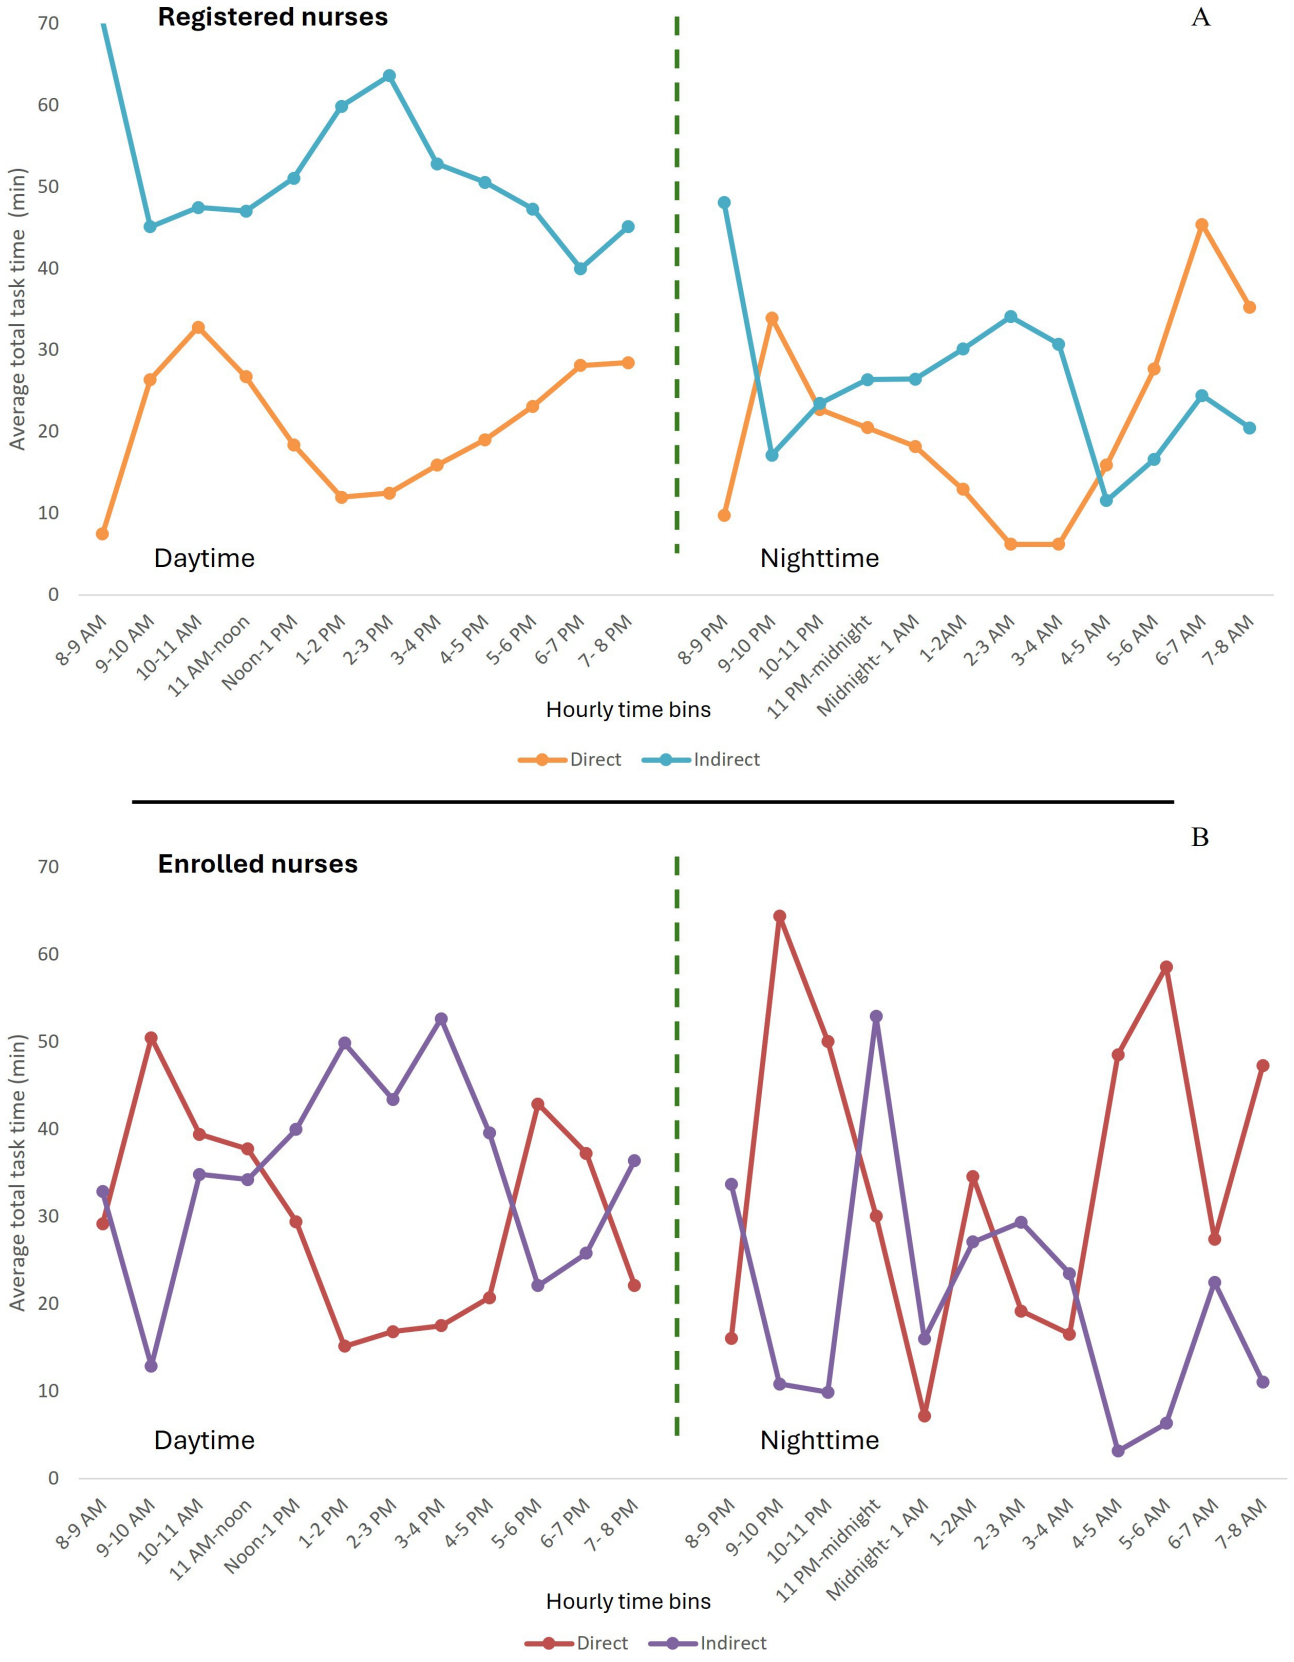
Figure 1. Total task load (minutes) by hour for a 24-hour period (task load by hour exceeds 60 minutes due to multitasking) for registered nurses (blue) and enrolled nurses (pink).



Task Type: Direct and Indirect Nursing Care Tasks

During the day, registered nurses spent an average of 30% (248 min; SD 74.6) of their time on direct clinical care and 70% (587 min; SD 98.9) of their time on indirect care tasks (Figure 2 and Table 2). Enrolled nurses, in contrast, spent an average of 46% (351 min; SD 52.5) of their time on direct care tasks and 54% (411 min; SD 73.2) of their time on indirect care tasks. At night, the proportion of time spent on direct care tasks increased for both groups: registered nurses spent an average of 42% (295 min; SD 78.9) of their time on direct care tasks, whereas enrolled nurses spent 61% (436 min; SD 98.5) of their time on direct care tasks, with the remainder dedicated to indirect care tasks (410 min, 58%; SD 67.2) for registered nurses, and 39% (275 min; SD 31.7) for enrolled nurses.

For registered nurses, indirect tasks dominated, with a consistently higher average total task load during the daytime (Figure 2). Direct task load typically remained at less than 30 minutes per hour, with a peak between 10 AM and noon and between 6 PM and 8 PM. At night, there was a noticeable drop in time spent on indirect tasks, and time spent on direct care tasks gradually decreased until 3 AM. From 3 AM onward, direct care tasks increased, peaking at 6 AM. For enrolled nurses, time spent on direct care tasks tended to dominate over time spent on indirect care tasks for much of the day, especially in the early morning and late afternoon, with a dip in the middle of the day. At night, there was considerable variability in both direct and indirect care tasks. There were notable spikes in direct care tasks (eg, around 11 PM-1 AM and 5 AM - 7 AM) and indirect care tasks (eg, 11 PM-midnight), suggesting time-specific care demands.

Figure 2. Direct and indirect total task load (minutes) by hour for (A) registered nurses and (B) enrolled nurses.

For registered nurses, medication handling (88/834 min, 10%), procedures (46/834 min, 5%), and patient communication (46/834 min, 5%) were the largest contributors to direct care task load during the day (percentage of total task time), with no change at night (Table 2). Staff communication (134/834 min, 16%), data entry into the medical record system (117/834 min, 14%), and record viewing (104/834 min, 12%) were the largest contributors to indirect care task load. At night, data entry and record viewing remained as the top tasks, but time spent on staff communication decreased, whereas handover time increased from 5% (38/834 min) during the day to 8% (59/705 min) at night.

XSL•FO
RenderX

For enrolled nurses, procedures (85/764 min, 11%), assisting with toileting or diaper changes (57/764 min, 8%), and patient communication (57/764 min, 8%) were the largest contributors to direct care task load during the day (percentage of total task time), with no change at night. In addition, the proportion of task time spent on vital sign taking increased from 4% (33/764 min) during the day to 12% (82/711 min) at night. Staff communication (107/764 min, 14%), data entry into the medical record system (90/764 min, 12%), and record viewing (60/764 min, 8%) were the largest contributors to indirect care task load during the day. At nighttime, data entry and record viewing remained high contributors to task time, but staff communication decreased to 2% (11/711 min), whereas observation of patients in the ward became the third largest contributor at 7% (52/711 min).

Multitasking Load

During a 24-hour period, registered nurses typically spent 209 (SD 51.8) minutes multitasking in the day and 117 (SD 41.0) minutes at night. For enrolled nurses, 152 (SD 54.7) minutes were spent multitasking in the day and 110 (SD 75.9) minutes at night. The frequency of occurrence varied over the course of the day (Figure 3). During the daytime, the period with the highest multitasking load was between 8 AM and 9 AM for registered nurses (33, SD 14.6 min) and enrolled nurses (25, SD 11.7 min), and the lowest multitasking load was observed between 6 PM and 7 PM for registered nurses and between 2 PM and 3 PM for enrolled nurses. At nighttime, the period with the highest level of multitasking was 6 AM to 7 AM for registered nurses (30, SD 33.1 min) and 9 PM to 10 PM for enrolled nurses (22, SD 16.3 min).

Figure 3. Average time (minutes) spent multitasking in each hour for a 24-hour period by registered nurses (blue) and enrolled nurses (pink).

Discussion

Principal Findings

To address ongoing workforce challenges, there is a pressing need for role redesign and the careful application of technology to support nursing practice. This study provided empirical insights into how nurses in general medicine wards spend their time across a 24-hour period, including the distribution of direct and indirect care activities and the occurrence of multitasking. This study is part of a wider program of work to inform how virtual nursing roles can be designed and integrated into ward workflows by identifying which tasks may be amenable to remote support and during which times support may be most beneficial.

Our findings show that nurses spent only 30% (247/834 min) to 46% (352/764 min) of their time on direct clinical care; the remainder was dedicated to indirect care tasks such as documentation and coordination. Task loads frequently exceeded 60 minutes of activity per hour, indicating significant multitasking and overlapping responsibilities. Such patterns reflect recognized inefficiencies in inpatient workflows, where competing demands require nurses to switch rapidly between tasks, increasing cognitive load and potential for error. We also observed predictable peaks in indirect care duties—particularly around early-morning and evening shift transitions—where

XSL•FO
RenderX

administrative and communication tasks accumulated. In contrast, night shift patterns demonstrated marked variability, with periods of low activity followed by compressed workloads toward the end of the shift, when cumulative fatigue is likely to be highest. These specific patterns represent risk-prone periods within the nursing workday.

From a service design perspective, these findings suggest that virtual nursing support may be particularly beneficial when targeted to predictable high-risk periods, such as shift transitions and late-night hours, rather than implemented as a constant or uniformly distributed resource. Our data show that documentation and coordination activities cluster at these transition points, creating periods where clinical sensemaking and narrative continuity may be compressed or fragmented. While often treated as discrete tasks, documentation and handover are essential to a nurse's understanding of patient care and response over time. Thus, the design of virtual nursing roles should support clinical sensemaking by assisting with preparatory documentation, information synthesis, and record completion while preserving the primary nurse's responsibility for clinical interpretation, evaluation, and relational care. In this way, virtual nursing supports continuity of care rather than displacing the ground nurse's knowledge of the patient.

Our analysis showed that nurses frequently experienced task loads exceeding 1 hour of activity per observed hour, reflecting substantial multitasking and the fragmented nature of nursing work [10,11,14,15]. While some multitasking may improve efficiency, excessive cognitive load increases the likelihood of errors and reduces care quality, underscoring the need to reconsider how workload is organized [19,20]. By mapping when peaks in documentation, coordination, and multitasking occur, we highlight concrete opportunities for virtual nursing integration. For example, indirect care tasks that cluster around shift handover—such as preparing documentation, updating EMR entries, and coordinating care plans—could be supported by virtual nurses operating remotely. Importantly, the high degree of task concurrency observed suggests that virtual nursing should prioritize offloading cognitively competing tasks (eg, documentation and coordination) rather than introducing additional parallel interactions that could further fragment attention.

Night shifts exhibited greater variability, particularly for enrolled nurses, with pronounced peaks and a late-shift surge, when fatigue is likely to impair performance and elevate error risk [21,22]. Prior studies have raised similar concerns, noting that staffing levels during night shifts often fail to meet patient needs, leading to increased stress and task compression or even unresolved tasks [23-25]. Although interventions such as scheduled napping and optimized lighting can mitigate fatigue [26-28], they do not address the underlying workload imbalance. These patterns point to specific opportunities for virtual nursing support, such as documentation, discharge preparation, remote monitoring, and assisting junior staff, to relieve peak pressures and enhance workflow continuity [29-31]. Aligning virtual nursing activity with these high-pressure windows offers a targeted approach to smoothing workflow peaks, reducing multitasking burden, and supporting safer, more sustainable practice.

Analysis of the types of nursing activities revealed that a substantial proportion of time was spent on indirect care tasks, particularly EMR documentation, by both registered and enrolled nurses. This aligns with extensive literature showing that administrative workload, especially documentation, is a major contributor to reduced direct care time, job dissatisfaction, and burnout [10,14,20,32,33]. From the perspective of the theory of human caring by Watson [13], excessive administrative demands diminish nurses' capacity to engage in the relational, patient-centered interactions that underpin caring-healing practices, such as being fully present, developing trust, and supporting patients' emotional and existential needs. Our findings reinforce these concerns by showing that administrative peaks occur at predictable times, particularly during shift changes, thereby reducing opportunities for therapeutic engagement. Rather than treating documentation reduction as a generic goal, our findings indicate that documentation support is most critical during temporally concentrated peaks—particularly at shift transitions, where administrative demands can displace opportunities for patient-facing care. These patterns highlight clear opportunities for workflow redesign, including improved handover protocols, EMR-integrated automation tools, and shifting routine documentation to virtual care teams or dedicated virtual administrative assistants. Early evaluations of virtual nursing models show promise in reducing documentation burden, improving workflow efficiency, and enhancing staff satisfaction [34-37]. Our data help identify where such support would be most impactful, ultimately enabling bedside nurses to devote greater attention to the caring practices central to the nursing profession.

Taken together, these insights offer timely evidence to guide the development of virtual nursing roles within inpatient workflows. Virtual nurses, equipped with real-time access to EMRs, vital sign dashboards, secure messaging, and telepresence tools, could assume a range of indirect care tasks—documentation, discharge coordination, remote education delivery, and virtual rounding [29-31,35-38]. Importantly, we should tailor support by staff role: for registered nurses, reducing documentation and coordination workload allows for greater focus on complex clinical care, whereas for enrolled nurses, virtual teams could assist with supervisory or routine administrative tasks [29-31,35-38]. Over time, this infrastructure also provides a foundation for automating selected processes with artificial intelligence–enabled tools, contributing to more scalable and sustainable workforce models.

At the same time, it is essential that the ethical considerations of virtual nursing are taken into account. Redistributing nursing work to virtual roles raises important ethical considerations related to professional responsibility, accountability, and the nurse-patient relationship. While indirect care activities may be performed remotely, clinical judgment, evaluation of patient responses, and ownership of care outcomes must remain with the primary nurse responsible for the patient. Therefore, our findings highlight the importance of designing virtual nursing models that reduce cognitive and administrative burden without fragmenting accountability or distancing nurses from patient care, ensuring that virtual support enhances—rather than

XSL•FO
RenderX

replaces—the ethical commitments embedded in bedside nursing practice.

Limitations

Our direct observations allowed us to gather unbiased data on nursing processes and report objectively on time use, overcoming the limitations of qualitative interview or survey data, which may be prone to bias. Our observation checklist was comprehensive, allowing for a fine-grained analysis of the task load. However, limitations must be acknowledged. We cannot ignore the Hawthorne effect, where staff may alter their behavior while being observed. We attempted to minimize this by briefing nursing teams and taking multiple sampling points over a 3-month period. There may also have been issues with observer variability. To minimize this risk, we conducted pilot work and training sessions with each observer to standardize the process. Observers were also encouraged to discuss issues and ask for clarifications during regular team meetings. Finally, our sampling took place during a 3-month period, which may not accurately reflect the average task load across the year.

Conclusions

This time-and-motion study documents the substantial and complex workload experienced by inpatient nursing staff over a 24-hour period across different nurse roles. The data reveal consistently high task demands, frequent multitasking, and pronounced peaks and troughs in workload throughout the day and night. These patterns suggest significant cognitive strain, with potential consequences for staff well-being and patient safety. These insights can inform the design of virtual nursing models or other technology-enabled workforce innovations. Future research should test and evaluate these models through staged implementation and outcome assessment, ensuring that virtual and hybrid care teams are safe, effective, and responsive to the realities of inpatient workflows.

Abstract

Background: Shift work disorder and insufficient sleep are prevalent among nurses, leading to fatigue, reduced well-being, and potential safety concerns. The increasing use of wearable sleep-tracking devices presents an opportunity to evaluate nurses' sleep quality objectively.

Objective: The primary objective was to evaluate the feasibility of wearable-based sleep monitoring and to obtain preliminary evidence of agreement with validated actigraphy among nurses. The secondary objective was to describe nurses' sleep characteristics and to examine exploratory associations between sociodemographic characteristics, shift patterns, sleep hygiene, and sleep parameters.

Methods: A 2-phase feasibility observational cohort study was conducted in a tertiary hospital in Singapore. In phase 1, 5 nurses concurrently wore a consumer-grade, wrist-worn Apple Watch Series 10 and a validated actigraph (GENEActiv; ActivInsights Ltd) for 2 weeks. Preliminary agreement between the Apple Watch and GENEActiv was examined using intraclass correlation coefficients. Feasibility was determined through wear-time compliance and data completeness. In phase 2, 50 nurses working rotating or single shifts completed demographic and work-related questionnaires and the Sleep Hygiene Index. Multiple linear regression analyses were performed to examine exploratory associations between selected covariates and sleep parameters, with adjustment for age, sex, BMI, parental status, workplace, total length of service, and sleep hygiene.

Results: The Apple Watch showed preliminary evidence of agreement with GENEActiv for total sleep time, in-bed wake time, and sleep efficiency (intraclass correlation coefficients of 0.95, 0.72, and 0.69, respectively), with high wear compliance and minimal missing data, supporting its feasibility for sleep monitoring. Mean total sleep time was 381 (SD 55) minutes, and mean sleep efficiency was 94.77% (SD 4.11%). Shift nurses reported poorer sleep hygiene than nonshift nurses; however, shift work status was not independently associated with sleep outcomes after adjustment. Higher BMI was associated with shorter total sleep time (unstandardized coefficient B=−3.76 min/kg/m²; P=.01), reduced rapid eye movement sleep (unstandardized coefficient B=−1.18 min; P=.03), shorter core sleep (unstandardized coefficient B=−2.72 min; P=.02), and reduced time in bed (unstandardized coefficient B=−4.05 min; P<.01=.008). Age was negatively associated with deep sleep duration, with older age associated with less deep sleep (unstandardized coefficient B=−1.00 min/y; P=.003).

Conclusions: Apple Watch–based monitoring was feasible and showed preliminary agreement with actigraphy. Nurses slept less than recommended, and BMI and age were associated with sleep outcomes in exploratory analyses. These findings support larger studies and workplace strategies to improve sleep opportunity and healthy sleep behaviors.

Introduction

Background

Insufficient sleep and sleep disorders are commonly identified health challenges among health care workers who perform shift work [1]. Shift work alters circadian rhythm, causes sleep disturbances, and affects physical and mental health, leading to poor work performance and affecting patient safety [2,3]. This is especially so for nurses who take on night shifts, where the irregularities between their internal circadian rhythms and the work requirements result in alterations in their sleep-wake cycles and light-dark cycles, which lead to a circadian rhythm

XSL•FO
RenderX

sleep-wake disorder known as shift work disorder [3]. Shift work disorder is characterized by chronic insomnia whereby individuals experience difficulties in falling asleep and staying asleep, as well as possible excessive sleepiness [4].

Prolonged irregular working hours increase nurses' vulnerability to the development of sleep disorders, including increased stress and anxiety, depressed mood, and reduced overall mental health [5]. The decrease in sleep quality among nurses has also been reported to increase sick leave days, lower job satisfaction, and burnout [6-8]. Studies have also highlighted possible associations between working night shifts and weight gain, obesity, breast cancer, cardiovascular disease, and metabolic disorders, including type 2 diabetes [9,10]. Regardless of the shift worked, nurses generally report poor sleep quality. Previous studies found that up to 63% of nurses reported poor sleep quality and that 68% highlighted insomnia-related concerns [11].

Sleep Patterns of Nurses on Shift Work

Nurses largely have no fixed work schedule; they have to manage and adjust their schedules according to their shifts. There is no fixed forward-cyclic rostering schedule. The sleep quality of nurses working on different shifts was evaluated in previous studies [12]. Nurses on the night shift generally had lower total sleep time, higher wake after sleep onset, and lower sleep efficiency during their work days when compared to those who worked day and evening shifts [13]. Nurses with rotational shifts in a counterclockwise rotation of more than 50% of shifts (night to evening to day shifts) reported poor sleep quality as well [12]. Whereas nurses who worked evening rotating shifts reported longer total sleep time when compared to those working day or night rotating shifts, as well as fixed day shifts. Furthermore, nurses on backward rotating–shift schedules also reported higher levels of sleep disturbances and less balanced sleep duration as compared to those on forward rotating–shift schedules [14]. Understanding sleep parameters of nurses working on different shifts is crucial to facilitate the arrangement of work shifts in the best possible manner to lower the impact of shift work on their sleep quality.

Sleep Hygiene Behaviors

Sleep hygiene primarily involves individual behaviors that facilitate sleep and minimize behaviors that prevent restful sleep [15]. Good sleep habits include avoiding late afternoon naps; minimizing caffeine, alcohol, and tobacco intake; reducing emotionally demanding activities during bedtime; ensuring a quiet and comfortable bedroom environment; and keeping to the same daily sleep schedule [16]. Inadequate sleep hygiene is defined in the International Classification of Sleep Disorders [17] as a type of sleep disorder due to individual activities that interfere with quality sleep and result in reduced daytime alertness.

The review of the literature found few studies exploring nurses' sleep hygiene behaviors. Recent studies have reported that poor sleep hygiene is associated with poor sleep quality and even with shift work disorder [18,19]. Various common poor sleep hygiene behaviors were identified among nurses, including going to bed at different times, waking at different times, going to bed feeling stressed or angry, as well as planning or worrying when in bed [18]. Poor sleep hygiene practices among nurses were also found to have higher insomnia and anxiety issues. Understanding sleep hygiene practices among nurses working in the acute care setting is crucial to increasing awareness about the importance of sleep hygiene and developing sleep hygiene interventions to improve nurses' sleep hygiene and sleep quality.

Sleep Monitoring Devices

The sensitivity and accuracy of actigraphy have been determined and are commonly used in clinical settings to evaluate sleep quantity and quality [20]. It is a small wristwatch-like device that is convenient for monitoring movements when nurses are at work. Actigraphy-based personal sleep monitoring devices help users establish an objective knowledge about their sleep patterns, including sleep quality, rhythms, and duration. Although actigraphy has been identified as the standard assessment for mobile sleep monitoring, recent rapid development of personal consumer devices has highlighted the possible validity of feasible alternative approaches to actigraphy in the measurement of sleep [21]. One of the advantages of using personal consumer devices is the lower cost, with accompanying additional features, when compared to traditional actigraphy devices. Other favorable features of personal consumer sleep devices include wireless or Bluetooth connections enabling close to real-time data processing and also contain other sensor measurements, including heart rate and respiratory rate, which may provide additional data for sleep algorithms.

Previous studies have evaluated the accuracy of Apple Watch, one of the most widely used consumer-grade sleep tracking devices [22,23]. Roomkham et al [23] compared the sleep parameters recorded on Apple Watch with Philips Actiwatch Spectrum Pro. They found Apple Watch to have overall accuracy (97%) and sensitivity (99%) in detecting actigraphy-defined sleep, and adequate specificity (79%) in detecting actigraphy-defined wakefulness. Apple Watch, on average, only overestimated total sleep time by 6.31 minutes and underestimated wake after sleep onset by 5.74 minutes [23]. Although previous findings have demonstrated that Apple Watch can provide reasonably accurate estimates of total sleep time in general adult populations, evidence remains limited regarding its performance in health care workers, particularly nurses who experience irregular schedules and fragmented sleep. Most validation studies have been conducted under controlled environments, and it is unclear whether consumer wearables perform similarly in occupational settings characterized by variable sleep timing and shift-work demands. Wearable-derived sleep metrics provide objective estimates of sleep timing, duration, continuity, and sleep-stage distribution; however, these data do not capture the behavioral and environmental circumstances that may influence observed sleep patterns. Assessing sleep hygiene alongside objective sleep measures is, therefore, warranted, as it allows consideration of modifiable practices such as irregular sleep schedules, caffeine consumption, presleep cognitive or emotional arousal, and bedroom conditions that may influence wearable-recorded sleep outcomes. The integration of objective sleep monitoring with sleep hygiene assessment may offer a more contextualized

XSL•FO
RenderX

understanding of nurses' sleep health and identify behavioral targets for future sleep-focused interventions.

To address these gaps, this study aimed to evaluate the feasibility of using a commercial sleep monitoring device and to obtain preliminary evidence of agreement with a validated research-grade actigraphy device among nurses working rotating shifts. Agreement was examined by comparing total sleep time, in-bed wake time, and sleep efficiency estimates from the Apple Watch and GENEActiv. Feasibility was examined through device wear compliance and the completeness of nightly data. The secondary aim was to examine how demographic characteristics, shift-work patterns, and subjective sleep hygiene behaviors relate to objectively measured sleep parameters among nurses working rotating shifts.

Methods

Design

A feasibility observational cohort study design was adopted.

Sample and Setting

A convenience sampling approach was used to recruit full-time registered nurses who are working in an acute care tertiary institution in Singapore from May 2025 to December 2025. The exclusion criteria included a history of psychiatric or neurological conditions, part-time employment, or long-term leave from work during the study period.

Sample size was not determined by a formal power analysis because this study was designed as a feasibility study [24]. For the first phase of the study, 5 participants were recruited. The focus of this phase was to conduct a local validation of Apple Watch against actigraphy, rather than to generate statistically powered estimates. Prior findings have demonstrated the relative accuracy of Apple Watch in estimating sleep and wake parameters when compared with polysomnography and actigraphy, showing moderate-to-high agreement for total sleep time and sleep efficiency [25]. In the second phase of the study, another 50 participants were recruited. This sample size was consistent with methodological recommendations for feasibility studies that emphasize obtaining preliminary estimates of outcome variability and adherence rates rather than hypothesis testing [26]. A sample of 55 participants would provide sufficient information on recruitment, attrition, and data completeness to inform the design of a future larger-scale study, while ensuring diversity of participants across demographics and shift patterns within the studied nursing population. The sample was, therefore, considered appropriate for the feasibility objectives of this study, including recruitment, device wear compliance, data completeness, and preliminary estimation of outcome variability, but was not intended to support definitive adjusted comparisons or multivariable regression modeling.

Data Collection

Recruitment and Baseline Data Collection

A study invitation email was sent to all nurses at the institution to solicit their participation. The email included the study details and eligibility criteria. Weekly email reminders were sent to encourage nurses to take part in the study. Written informed consent was obtained from interested participants who approached the study team.

Upon obtaining consent, baseline data, including sociodemographic information (age, sex, race, BMI, marital status, number and ages of children, caregiving for an older family member, educational qualifications, and smoking status), were collected. Work-related information was also obtained, including shift patterns (single-shift duties included day, night, or office hours; rotating-shift duties included 2- or 3-rotation schedules comprising day, evening, and night shifts), clinical areas of work, years of experience in the current work location, job grade, and total length of service. Feasibility was assessed through device wear compliance and the extent of missing sleep data.

Measurement of Sleep Time and Other Vital Signs

For the first phase of the study, 5 nurses wore an Apple Watch Series 10 and a GENEActiv actigraph device (ActivInsights Ltd) during sleep for 2 weeks. All Apple Watch devices, paired iPhones (Apple), and GENEActiv devices used in this study were department-owned equipment designated for research purposes only. The Apple Watch and GENEActiv devices were provided to participants only for the duration of the monitoring period and were returned to the study team after data collection. The Apple Watch Series 10 was selected as the consumer wearable device for this feasibility study because Apple Watch is widely used, is familiar to many users, and is supported by prior validation evidence for estimating sleep duration [23]. Its wrist-worn format, automated sleep tracking, and integration of movement and physiological sensor data also made it a practical option for short-term sleep monitoring among nurses working irregular schedules. Participants were briefed by the study team to manually activate "Sleep Mode" on the Apple Watch before going to sleep and to deactivate it upon waking. For GENEActiv, participants were not required to activate or deactivate the device; sleep start and end times were derived using participants' reported sleep and wake times to define the sleep period for analysis. Participants were reminded during the study briefing to record their sleep and wake times accurately throughout the monitoring period, and daily reminders were provided by the study team to prompt participants to document their sleep and wake times. GENEActiv has been validated against polysomnography and demonstrated reliable performance in detecting sleep and wake patterns (intraclass correlation coefficients [ICCs] of 0.79-0.85) for sleep parameters [27]. Total sleep time, in-bed wake time, and sleep efficiency were compared between GENEActiv and Apple Watch. Apple Watch data were synchronized to the paired iPhone and retrieved from the Apple Health dashboard after each participant completed the monitoring period [28]. GENEActiv raw accelerometer data were extracted in .bin format, with Actiwatch Data files or comma-separated values files generated using ActivInsights software where required [29]. The sleep report was generated using the Actigraphy sleep toolkit [30]. Sleep data were extracted from the Actigraphy sleep report after each participant completed monitoring. All extracted sleep data were reviewed by the principal investigator for completeness and consistency before analysis, while the principal investigator remained blinded to participants' shift roster.

XSL•FO
RenderX

In the second phase of the study, additional sleep metrics from the Apple Watch were collected, including time in bed, which was measured from sleep start to sleep end; in-bed wake time; and amounts of rapid eye movement (REM), light (core), and deep sleep during the time spent in bed. Sleep efficiency was manually calculated as the percentage of time spent asleep while in bed, defined as the total sleep time divided by the time in bed and multiplied by 100.

Sleep Hygiene

The Sleep Hygiene Index was used to evaluate the sleep hygiene behavior of the participants. It was administered at baseline through an online survey before the start of sleep monitoring. The Sleep Hygiene Index is a self-administered 13 items designed to assess environmental and behavioral variables that could disrupt sleep prior to bedtime, including inconsistent bedtimes, feelings of stress, anger, or worry, engaging in stimulating activities in bed such as watching television, consuming caffeine, or exercising right before bedtime, as well as the comfort level of the bedroom environment [31]. Participants were asked to report on the frequency of engagement in the specific behavior (0="never," 1="rarely," 2="sometimes," 3="frequently," and 4="always"). Total scores ranged from 0 to 52, with a higher score representing more maladaptive sleep hygiene practices. The Sleep Hygiene Index scores were presented as percentile rank, with scores above 50 indicating more disruptive sleep behaviors than average, to the extent that they would be more likely to result in poor sleep quality [31]. Scores 35 and above are considered poor sleep hygiene, 27 to 34 are considered normal, and below 26 are considered good sleep hygiene status. The Sleep Hygiene Index reported adequate reliability and validity [31]. The items from the Sleep Hygiene Index were developed based on the diagnostic criteria for insufficient sleep hygiene according to the International Classification of Sleep Disorders by the American Sleep Disorders Association [4]. The Sleep Hygiene Index reported satisfactory Cronbach α (0.66) and good test-retest reliability (r=0.71) [31].

Ethical Considerations

Ethical approval was obtained from the SingHealth Centralised Institutional Review Board, Singapore (ECOS Ref: 2024 - 3932). A participant information sheet detailing the study purpose, procedures, and voluntary nature was provided. Written informed consent was obtained from each participant before participation. Participants' privacy was protected, and the confidentiality of their identities and study data were maintained throughout the study. Participants received reimbursement for the time spent participating in the study.

Data Analysis

Data were entered and analyzed using SPSS version 25.0 (SPSS Inc).

The normality of continuous variables was examined using Shapiro-Wilk tests. Descriptive statistics were computed to summarize participants' demographic, occupational, and behavioral characteristics. Continuous variables were reported as means with SDs, while categorical variables were summarized as frequencies and percentages.

In this feasibility study, preliminary agreement between Apple Watch and GENEActiv was assessed using the ICC for total sleep time, in-bed wake time, and sleep efficiency. Given the small validation sample (n=5), these analyses were intended to provide preliminary evidence of agreement rather than to establish measurement accuracy. ICC values below 0.50 were considered poor, 0.50 to 0.74 moderate, 0.75 to 0.90 good, and above 0.90 excellent [32]. Total sleep time, in-bed wake time, and sleep efficiency were compared directly between devices without epoch alignment [33].

Feasibility was determined by calculating device wear compliance and the completeness of nightly sleep data over the 14-night monitoring period, with higher percentages indicating better acceptability and integration of the device into participants' routines. Wear compliance was expressed as the percentage of nights in which the device was worn. Completeness of nightly data was calculated as the percentage of nights that yielded valid sleep recordings out of the total number of nights. A valid sleep recording was defined as a night in which the device was worn during the intended sleep period and produced an interpretable sleep output with corresponding sleep start and end times. For phase 1 device-comparison analyses, a night was considered valid only when both Apple Watch and GENEActiv had usable data for the same reported sleep episode. Nights with partial recordings, implausible or incomplete sleep or wake entries, nonwear, incorrect wear, synchronization failure, or no recorded sleep output were treated as invalid and excluded from the analysis. Missing data were categorized as nonwear, incomplete or invalid sleep or wake entries, device synchronization failure, or no recorded output despite device wear.

Associations between demographic, occupational, and behavioral variables (age, sex, BMI, shift duties, work unit, parental status, total length of service, and Sleep Hygiene Index) and sleep outcomes were examined using multiple linear regression. Separate multiple linear regression analyses were performed for each sleep parameter: total sleep time, REM sleep, core and deep sleep, time in bed, in-bed wake time, and sleep efficiency. Given the feasibility design and modest sample size, all adjusted analyses were treated as exploratory. Covariates were limited to a small set of demographic, occupational, and behavioral factors considered clinically relevant to nurses' sleep. This variable-selection strategy reduced, but did not eliminate, the risk of overfitting, particularly for categorical predictors that increased the number of model parameters. No formal adjustment was made for multiple comparisons. Accordingly, results were interpreted with reference to effect estimates, CIs, and patterns of consistency across related outcomes rather than statistical significance in isolation. Sleep-stage variables were also considered descriptively, as they represent interdependent components of total sleep time. Statistical significance was set at P<.05.

Results

Participant Characteristics

Fifty-five nurses participated, of whom 36 (65.5%) worked rotating shifts and 19 (34.5%) were on single-shift duties (Table

XSL•FO
RenderX

1). The mean age was 36 (SD 9) years, and most participants were female individuals (92.7%). The mean BMI was 24 (SD 5.3) kg/m², with 43.6% (n=24) overweight or obese (BMI>23 kg/m^2). Around half (n=26, 47.3%) were married, and fewer had children (n=19, 34.5%). Most respondents were graduates of a baccalaureate nursing degree with honors program (60.0%). The mean total length of service was 12.2 (SD 10) years, significantly longer among nonshift nurses compared with shift nurses (15 vs 5.5 y; *P*=.02). The mean Sleep Hygiene Index score was significantly higher among shift nurses (19.8 vs 15.6; *P*=.01), indicating poorer sleep hygiene in this group. Other sociodemographic variables did not differ significantly between groups (Table 1).

Agreement and Feasibility of the Apple Watch

Five nurses completed up to 14 consecutive nights of concurrent monitoring with the Apple Watch and GENEActiv. Apple Watch showed preliminary agreement with GENEActiv for total sleep time, in-bed wake time, and sleep efficiency (ICC=0.95, 0.72, and 0.69, respectively; Table 2). Figure 1 shows nightly total sleep time for valid paired recordings only. Across participants, the 2 devices showed closely aligned total sleep time patterns.

In phase 1, 5 nurses contributed 70 expected monitoring nights over 14 days. The Apple Watch was worn on 67 of 70 nights, giving a wear compliance of 95.7%, while 3 nights were classified as nonwear. Of the 67 nights when the Apple Watch was worn, 56 nights yielded valid Apple Watch sleep recordings, giving a data completeness rate of 83.6% among worn nights. The remaining 11 worn nights had no Apple Watch sleep output despite the device being charged and initialized before use and were therefore classified as device-related or synchronization-related data loss. For GENEActiv, 67 of 70 expected nights yielded valid recordings, while 3 nights were missing because the device was not worn. Paired device-comparison analyses were restricted to nights with valid recordings from both the Apple Watch and GENEActiv.

Across the 55 nurses, there were 770 expected nights of Apple Watch monitoring. The Apple Watch was worn on 755 nights, corresponding to 98.1% wear compliance, while 15 nights were classified as nonwear. Among the 755 worn nights, 705 yielded valid Apple Watch sleep recordings, corresponding to 93.4% data completeness among worn nights. The remaining 50 worn nights had no recorded Apple Watch sleep output despite device charging and initialization, and these nights were classified as device-related or synchronization-related data loss. Thus, missing Apple Watch data were separated into nonwear nights and nights with device-related missing output despite reported device wear.

Table . Intraclass correlation coefficients (ICC) examining preliminary agreement between the Apple Watch and GENEActiv for total sleep time, in-bed wake time, and sleep efficiency (N=5)[a].

Sleep parameters	ICC (95% CI)	*P* value[b]
Total sleep time (min)	0.95 (0.06 to 1.00)	<.001
In-bed wake time (min)	0.72 (–0.05 to 0.97)	.05
Sleep efficiency	0.69 (–0.09 to 0.96)	.03

[a]ICCs represent comparisons between the Apple Watch and GENEActiv. Reliability is deemed "poor" if the ICC is <0.4, "fair" if between 0.4 and 0.59, "good" if between 0.60 and 0.74, and "excellent" if above 0.75.

[b]Significant at $P<.05$.

Figure 1. Nightly total sleep time recorded by the Apple Watch and the GENEActiv across 14 nights for (A-E) 5 nurses. Note that the missing data reflect nights when either device was not worn, was worn incorrectly, or had incomplete sleep or wake time entries, and these nights were excluded from the analysis.

Sleep Parameters by Shift Type

The comparison of sleep parameters between nurses working single-shift duty (day, night, or office hours) and those on rotating-shift duties (day, afternoon, and night) is reported in Table 3. Overall, the nurses obtained a mean total sleep time of 380.55 (SD 55.08) minutes. Nurses on rotating shifts recorded a mean total sleep time of 382.03 (SD 55.92) minutes compared

XSL•FO
RenderX

with 377.76 (SD 55.85) minutes among single-shift nurses; this difference was not significant in the unadjusted analysis (mean difference=−4.27, 95% CI −35.87 to 27.33 min; *P*=0.79) and remained nonsignificant after adjustment for age, sex, BMI, presence of children, workplace, total length of service, and sleep hygiene score (adjusted mean difference=−7.38, 95% CI −40.74 to 25.99 min; *P*=.66). Similarly, no significant group differences were found for REM, core, or deep sleep in either unadjusted or adjusted analyses (*P*>.05).

The mean time in bed for all nurses was 401.45 (SD 54.57) minutes, the mean wake time in bed was 19.79 (SD 13.76) minutes, and the average sleep efficiency was 94.77% (SD 4.11%). Mean time in bed was similar between nurses on single shifts (402.46, SD 55.09 min) and rotating shifts (400.92, SD 55.07 min), with no statistically significant differences before or after covariate adjustment. Similarly, in-bed wake time and sleep efficiency did not differ significantly by shift type.

Table . Sleep parameters of nurses with different shifts.

Sleep parameters	All nurses (N=55), mean (SD)	One-shift duty (day, night, or office hours; n=19), mean (SD)	Rotating-shift duties (morning, afternoon, and night; n=36), mean (SD)	Unadjusted mean difference[a] (95% CI)	*t* test (*df*)	*P* value	Adjusted mean difference[b] (95% CI)	*P* value [c]

Associations Between Selected Variables and Sleep Outcomes

Results from multiple linear regression analyses examining exploratory associations between selected variables and sleep parameters derived from Apple Watch devices were presented in Table 4. Given the modest sample size relative to the number of predictors and outcomes, these findings should be regarded as exploratory and hypothesis-generating. After adjustment for age, sex, BMI, shift duties, parental status, work unit, total length of service, and Sleep Hygiene Index, several associations were observed. Higher BMI was associated with shorter total sleep time (unstandardized coefficient *B*=−3.76, 95% CI −6.70 to −0.81 min/kg/m²; *P*=.01), reduced REM sleep duration (unstandardized coefficient *B*=−1.18, 95% CI −2.24 to −0.12 min; *P*=.03), and shorter core (light) sleep duration (unstandardized coefficient *B*=−2.72, 95% CI −5.04 to −0.40 min; *P*=.02). BMI was also associated with reduced time in bed (unstandardized coefficient *B*=−4.05, 95% CI −6.99 to −1.11 min; *P*=.008). Age was negatively associated with deep sleep duration, with older age associated with less deep sleep (unstandardized coefficient *B*=−1.00, 95% CI −1.65 to −0.35 min/y; *P*=.003). Overall, sex, parental status, work unit, total length of service, and Sleep Hygiene Index were not significantly associated with total sleep time, REM sleep, deep sleep, in-bed wake time, or sleep efficiency (*P*>.05).

Discussion

Principal Findings

This study evaluated the feasibility of consumer wearable sleep monitoring among nurses and obtained preliminary evidence of agreement with validated actigraphy in a small validation sample for total sleep time, in-bed wake time, and sleep efficiency. These findings are consistent with previous studies showing that consumer sleep technologies can provide reasonably accurate estimates of total sleep duration compared with research-grade actigraphy devices [33,34]. Much of the existing literature on nurses' sleep has relied on subjective measures, which capture perceived sleep quality but may not accurately quantify sleep duration, sleep-wake patterns, or awakenings. Previous studies have also shown limited agreement between subjective sleep reports and objective measures among nurses [35]. Accordingly, actigraphy and wearable devices are increasingly used to support continuous sleep assessment during clinical schedules [36], although further validation and longer monitoring periods are needed to establish their accuracy and utility in occupational settings [37].

Wear compliance and data completeness supported the feasibility of Apple Watch monitoring in this setting, although some data loss resulted from nonwear or technical issues, as expected in real-world wearable studies [38,39]. Beyond measurement, wearable feedback may complement sleep education by increasing awareness of sleep routines, consistent with behavioral self-efficacy and behavior change models [40,41].

Nurses slept an average of 381 minutes, or approximately 6.4 hours per night, which is below the recommended 7 to 9 hours for adults [42]. Although sleep efficiency was high (94.77%), this should not be interpreted as unequivocal evidence of robust sleep quality. In the context of short total sleep duration and limited time in bed, elevated sleep efficiency may instead reflect constrained sleep opportunity, whereby nurses slept for most of the limited time available rather than achieving sufficient or restorative sleep. This finding is consistent with studies reporting

XSL•FO
RenderX

a high prevalence of poor sleep quality and disrupted sleep among nurses in Asian and shift-working populations [43-46]. Insufficient sleep has been associated with fatigue, impaired cognitive and psychomotor performance, burnout, emotional dysregulation, and occupational fatigue, underscoring the clinical relevance of the short sleep duration observed in this cohort [47-51].

Contrary to expectations, shift duty status was not significantly associated with any sleep parameter after covariate adjustment. Instead, BMI showed the most consistent associations, with higher BMI associated with shorter total sleep time, reduced REM and core sleep, and less time in bed. Although shift nurses reported poorer sleep hygiene than nonshift nurses, Sleep Hygiene Index scores were not independently associated with sleep outcomes in the adjusted models. These findings suggest that individual lifestyle and behavioral factors may be associated with sleep outcomes beyond work schedule alone. Similar observations have been reported in studies showing associations between daily routines, diet, sleep timing around shifts, and sleep quality among nurses [52]. Multiple correlated sleep outcomes were examined across several predictors without adjustment for multiple comparisons; therefore, the regression findings should be interpreted cautiously, with greater emphasis on effect sizes, CIs, and consistency across related outcomes rather than isolated *P* values.

Age also emerged as a significant determinant of sleep outcomes, with older nurses showing reduced deep sleep duration. This pattern is consistent with well-established evidence showing that deep sleep declines across adulthood as a result of age-related changes in cortical activity and sleep homeostasis [53]. Recent studies using both consumer wearables similarly reported a reduction in deep sleep with age among working adults, including health care staff [38,54]. Given that deep sleep contributes to physiological recovery, cognitive functioning, and metabolic regulation, reduced deep sleep among older nurses may have important consequences for fatigue, resilience, and day-to-day clinical effectiveness. Supporting older nurses through workplace policies and tailored sleep-health interventions may be an important component of broader efforts to support and maintain the long-term sustainability of the nursing workforce.

Implications for Nursing Practice

These findings have practice-relevant implications for the nursing workforce. Organizational strategies should prioritize sleep opportunity and fatigue risk management through rostering review, protected rest periods, and minimization of excessive consecutive shifts or overtime. Older nurses may also benefit from tailored fatigue-management support.

Wearable sleep tracking may complement staff well-being initiatives by providing objective feedback alongside sleep education, particularly for nurses who underestimate sleep disruption based on self-report alone. Accordingly, any recommendation for broader Apple Watch use should be balanced against considerations of cost, scalability, and local implementation needs, including whether lower-cost wearables, validated sleep questionnaires, or targeted actigraphy may provide a more proportionate approach for workplace sleep-health initiatives.

Third, the association between higher BMI and poorer sleep parameters underscores the importance of adopting a holistic approach to health promotion within the nursing workforce. Initiatives that support physical activity, healthy nutrition, weight management, and stress regulation may contribute not only to improved sleep outcomes but also to overall well-being.

Finally, poorer sleep hygiene among shift nurses indicates the value of incorporating practical sleep-hygiene guidance into staff well-being programs across shift types.

Limitations

Several limitations should be considered. First, the validation component involved only 5 nurses; therefore, the device-comparison findings should be interpreted as preliminary feasibility evidence rather than established measurement accuracy. Although small samples are acceptable in feasibility studies, recruiting the cohort from a single institution may limit generalizability. An a priori power analysis was not conducted because the study primarily evaluated feasibility. The adjusted analyses included several covariates and multiple interdependent sleep outcomes relative to the sample size and may therefore have been underpowered, overfitted, or imprecise. As no adjustment for multiple comparisons was applied, statistically significant findings should be regarded as exploratory and interpreted cautiously until confirmed in adequately powered studies with prespecified analytic plans.

Self-selection bias may also have occurred, as nurses who volunteered may have had a greater interest in sleep monitoring or have perceived sleep difficulties. Self-reported questionnaires, including the Sleep Hygiene Index, may be affected by recall or social desirability bias. The nonsignificant associations between Sleep Hygiene Index scores and objective sleep outcomes should be interpreted cautiously, as they may reflect measurement limitations, restricted variability in this relatively homogeneous cohort, and limited power to detect small associations. In addition, manual inspection of sleep data was performed only by the principal investigator; although the principal investigator was blinded to participants' shift rosters, the absence of independent interrater verification may have introduced subjective judgment in determining data completeness and consistency.

Chronotype was not assessed in this study, although individual circadian preference may influence tolerance for shift work and could partly explain why shift status was not independently associated with sleep outcomes. Future studies should examine whether chronotype moderates the relationship between shift schedules and sleep outcomes to guide chronobiologically informed scheduling. Finally, although total sleep time, in-bed wake time, and sleep efficiency were compared between the Apple Watch and the GENEActiv, device-specific sleep-window definitions, algorithms, scoring rules, and firmware updates may affect wake-related estimates and reproducibility over time.

Despite these limitations, this study provides objective sleep data among nurses in an Asian context, as well as preliminary evidence supporting the feasibility of Apple Watch–based

XSL•FO
RenderX

monitoring and its agreement with validated actigraphy for selected sleep parameters. The observed associations remain exploratory given the observational design and modest sample size.

Conclusions

This study showed that nurses obtained less sleep than recommended, underscoring concerns about sleep opportunity and recovery in this workforce. The Apple Watch provided preliminary evidence of feasibility and agreement with GENEActiv for total sleep time, in-bed wake time, and sleep efficiency in a small validation sample. BMI and age were associated with sleep outcomes in exploratory analyses. These findings support workplace strategies that combine sleep education, sleep hygiene training, and broader fatigue-management efforts to promote healthier sleep among nurses.

Acknowledgments

Apple Inc provided Apple Watch devices for the research. Apple was not involved in the design of the research, nor was it involved in the collection, analysis, or interpretation of the research data or in the content of this or any related publication. Abstract

Background: Routinely collected nursing real-world data (RWD) offer opportunities for nursing research to generate new knowledge and to improve quality of care. Furthermore, advanced analytics with nursing routine data opens the development of predictive models that support risk detection and decision support. However, using RWD in nursing remains challenging due to insufficient data standardization, variable data quality, and difficulty for organizations implementing a targeted data strategy for the secondary use of nursing data. To address this gap, we developed the NuDaK nursing data strategy framework as a practical guide to enable and optimize the secondary use of routinely collected nursing documentation data.

Objective: This study aimed to evaluate the completeness and applicability of the NuDaK framework for the secondary use of nursing routine data in a clinical nursing setting.

Methods: We conducted a formative feasibility study in collaboration with a large acute care hospital in Austria. The NuDaK framework was piloted on a surgical ward and evaluated across 4 implementation phases. Data were collected via phase-specific workshops and project meetings, continuous self-evaluation protocols by the project lead, and a final online focus group interview. Data were analyzed using deductive qualitative content analysis regarding the completeness and applicability of NuDaK. Evaluation results were aggregated and used to update NuDaK.

Results: The 4 core NuDaK aspects (“Purpose & Benefits,” “Dataset & Nursing Documentation,” “Data Modeling & Software Requirements,” and “Data Integration & Data Quality”) were confirmed as conceptually complete. Based on the evaluation results, NuDaK was updated by (1) adopting a circular structure with 4 temporal phases, (2) defining interdisciplinary stakeholder involvement across phases, (3) specifying professional roles and responsibilities across phases, and (4) integrating an iterative nursing information model spanning dataset development, specification, and refinement. Further NuDaK additions comprise a data quality concept with operationalized dimensions and validation procedures.

Conclusions: The NuDaK nursing strategy framework was refined through real-world piloting. It now provides organizations and researchers with a nursing-specific, end-to-end nursing data strategy to enable systematic RWD use. While its feasibility was demonstrated in a real-world nursing setting, further implementation studies should assess transferability across heterogeneous institutions with different documentation systems, governance structures, and levels of digital maturity.

nursing informatics; nursing real-world data; secondary use of nursing data; data strategy framework; nursing outcome analytics

Introduction

Background

Digitization in nursing care has advanced considerably. In Germany, digital nursing and treatment documentation averaged 68.4% in 2023 [1]. Similar levels are reported in Austria and Switzerland, where 76% of nursing documentation in hospitals is electronic and 88% of facilities use IT-supported nursing documentation in at least half of their units [2]. Likewise, in the United States, over 96% of hospitals used an electronic health record (EHR) system in 2022 for clinical notes, most with integrated digital nursing documentation [3].

This digital transformation not only changes documentation processes but also involves the routine collection of vast amounts of real-world data (RWD).

RWD are defined as data routinely collected during care provision relating to patient health status or the delivery of health care from various sources, for example, EHRs and documentation systems, disease-specific medical research registries, and data from wearable or mobile devices [4].

XSL•FO
RenderX

RWD can support both nursing research and quality improvement. They offer several advantages because RWD are routinely collected from various health-related sources; they can provide comprehensive and timely representations of patient care and care delivery [5]. The use of RWD in nursing research can help generate evidence-based knowledge for practice, improve the quality of patient care, and further develop nursing practice by, for example, assessing the effectiveness of nursing interventions in achieving specific nursing outcomes based on routine data. In addition, RWD-based analyses can support personalized, patient-centered care while optimizing resource use [6,7]. Advanced analytics with nursing routine data also opens the development of predictive models that support applications such as risk detection and decision support [8-10].

Despite these potentials, the secondary use of nursing RWD remains limited. One major challenge is that nonstandardized data entry limits data reuse. In many settings, standardized nursing terminologies are insufficient or inconsistently applied [2]. This lack of standardization makes it difficult to harmonize and integrate data for meaningful analysis [4,11]. Additionally, the widespread use of free-text documentation, while valued by clinicians for flexibility and completeness, makes data analysis difficult [2,12].

Another challenge is low data quality. Incomplete or incorrect documentation can lead to data gaps and analytical errors and reduce the reliability and validity of results [4].

Finally, many institutions lack a comprehensive data strategy that addresses all aspects relevant to nursing research and nursing outcome evaluation [2]. Without a coordinated approach, data are often collected in isolated application systems, using inconsistent formats and varying documentation standards and terminologies. This fragmentation limits data interoperability, complicates data linkage across settings, and restricts the ability to aggregate information for large-scale analyses [13].

To address these challenges, the literature describes several foundational components that should be addressed to enable the secondary use of nursing RWD. A key component is the standardization and structured documentation of nursing documentation. The consistent use of standardized nursing terminologies and structured data formats enhances the ability to characterize nursing care and analyze its effects on nursing outcomes. Structured and standardized documentation practices are essential for ensuring high data quality, interoperability, and meaningful integration with other clinical data sources [14,15]. Equally important is the precise definition of secondary use purposes and the identification of outcome indicators. Together, these elements provide the foundation for outcome-oriented and evidence-based nursing research [16,17]. Nursing-sensitive outcome indicators serve as key measures in this context. They capture outcomes directly influenced by nursing care, such as patient falls, pressure injuries, pain management, or infection rates, and provide a quantitative basis for evaluating care quality and effectiveness [18-26].

Another essential component for the secondary use of nursing data is the establishment of a defined dataset. A clearly specified dataset determines which data elements are relevant for describing nursing practice and nursing outcomes, ensuring that the collected information is complete, consistent, and comparable across institutions and care settings [27,28].

To ensure that these data are reliable and interpretable, data information models specify the structure and relationships among these datasets and define their meaning in a standardized form. These models bridge clinical and technical perspectives by translating nursing knowledge into formal data specifications, reducing ambiguity and enabling accurate data capture in electronic documentation systems [27,29].

A further critical component is data quality, which determines the reliability and validity of any secondary analysis. High-quality nursing data to be used for RWD analysis must be complete, correct, current, consistent, and plausible, which is supported by systematic data validation and transparent data reporting [30-33].

Finally, data integration is required to consolidate data from multiple sources into an analysis-ready structure (eg, via a data warehouse or data mart), which typically requires close interdisciplinary collaboration among IT professionals, data scientists, and nursing researchers to ensure clinical relevance and technical feasibility [16].

While these components represent core building blocks identified in the literature for enabling the secondary use of nursing RWD, existing frameworks for this task often address only selected aspects rather than providing an integrated, nursing-specific strategy.

The SPIRIT (Systematic Planning of Intelligent Reuse of Integrated Clinical Routine Data) framework offers a secondary use strategy for the entire organization, comprehensive analyses to define system and user requirements, and the implementation of clinical data integration, management, and analysis solutions. However, it does not address specific nursing outcomes and nursing routine data [16].

The framework for mining and analyzing standardized nursing care plan data facilitates the extraction of valuable knowledge from nursing care plan data, demonstrating its applicability in improving nursing outcomes, supporting nursing staff, and enhancing administrative functions [9]. However, the handling of nonstandardized care plan data remains insufficiently addressed, particularly in terms of data harmonization and quality analysis, which are essential to ensuring the reliability and interoperability of the extracted information. The Health Data Quality Framework provides an automated approach for assessing and visualizing the quality of EHR data to support analytics such as predictive modeling and quality measures [33]. This framework primarily targets data quality and thus does not constitute an end-to-end strategy for the reuse of nursing routine data.

Finally, the Governance Framework developed for secondary use of routine health care data in nursing homes outlines governance, legal, and ethical principles for responsible reuse [34]. This framework is not intended to be a comprehensive nursing data strategy across the full life cycle.

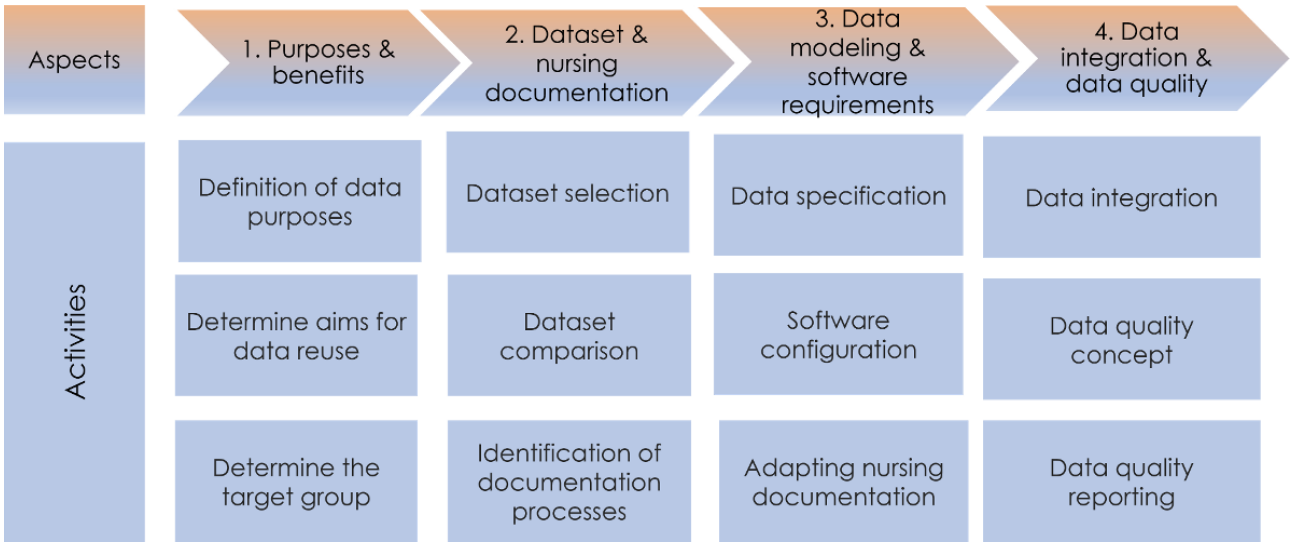
Overall, most available frameworks focus on individual dimensions (eg, governance, data quality, or analytic reuse)

XSL•FO
RenderX

without systematically combining all key components into a coherent, nursing-specific data strategy.

In summary, no existing framework comprehensively supports the secondary use of routinely collected nursing documentation data in a nursing-specific way. Current approaches do not adequately address specific nursing outcomes and the particular characteristics of nursing routine data. As a result, an important gap remains in how nursing RWD can be systematically leveraged for nursing-related purposes.

To address this gap, we developed the NuDaK nursing data strategy framework to enable and optimize the secondary use of routinely collected nursing documentation data.



NuDaK does not aim to be universally exhaustive but focuses on addressing nursing data, nursing-related outcomes, and the specific characteristics of routine nursing data. The NuDaK framework serves as a practical guide for both organizations and research teams by structuring how clinical routine data can be prepared, governed, and analyzed for nursing purposes.

In organizational settings, within single institutions or across organizations, NuDaK supports assessing the effectiveness of nursing interventions on nursing outcomes, strengthening nursing quality management, enabling personalized patient-centered care while optimizing resource use, and informing workflow steering.

In research settings**,** NuDaK underpins robust evidence generation in nursing by improving data quality, standardization, and governance, thereby enabling advanced analytics such as data mining, AI-based predictive modeling, risk detection, and decision support.

The NuDaK framework encompasses 4 interrelated aspects that reflect the key components of a comprehensive data strategy (see Figure 1 for an overview) [35,36].

Figure 1. NuDaK nursing data strategy framework (2022) for the secondary use of routine nursing data.

1. Defining the purposes and benefits of using routinely collected data
2. Establishing a standardized nursing dataset and adapting nursing documentation to nursing workflows
3. Data modeling and specification of software requirements
4. Implementing processes for data integration and quality assurance [35,36]

Some information on NuDaK has been published in [35,36]. While NuDaK was built on the results of a narrative-integrative literature review with conceptual synthesis, a comprehensive description and evaluation have not yet been conducted. This is therefore the objective of this paper.

Objective

This study aimed to evaluate the completeness and applicability of the NuDaK data strategy framework in a real clinical nursing setting and, based on these findings, to refine NuDaK as a practical guide for organizations and researchers to enable the secondary use of routinely collected nursing documentation data.

Methods

Study Design

This study is reported in accordance with the STARE-HI (Statement on Reporting of Evaluation Studies in Health Informatics) guideline to enhance the quality and transparency of reporting for quantitative and qualitative health informatics evaluation studies. In line with STARE-HI, the *Methods* section is structured to provide sufficient detail on the study design and methods used in this study [37].

We conducted a 1-year formative feasibility study (February 2023 to June 2024) to pilot and evaluate the NuDaK framework in a real clinical nursing setting. The evaluation focused on 2 primary dimensions: (1) applicability (how well it fits the health care environment) and (2) completeness (whether it covers all necessary aspects and activities comprehensively).

The study used 3 complementary evaluation methods: a formative qualitative external evaluation, a qualitative self-evaluation, and an online focus group interview at the end of the piloting phase.

XSL•FO
RenderX

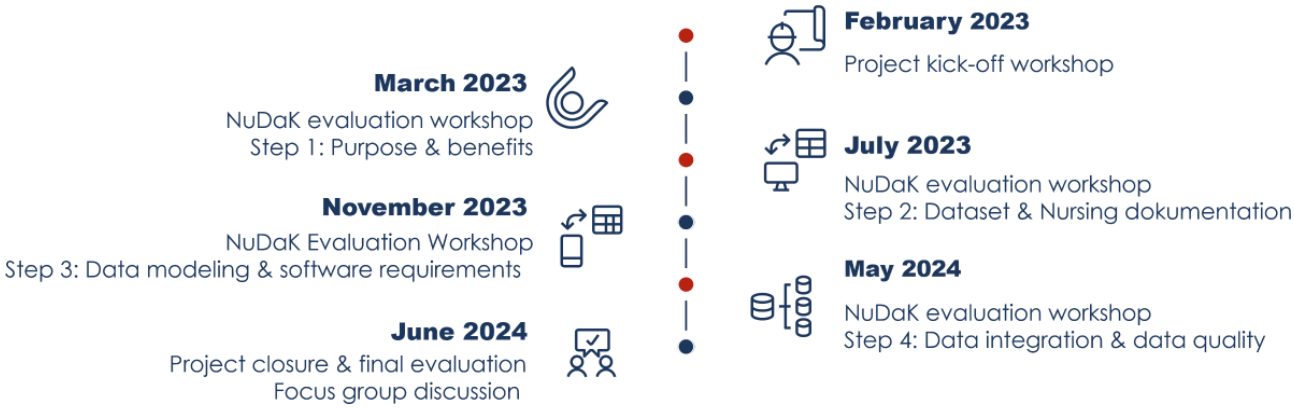
Theoretical Background

Formative evaluations are particularly employed when a program, product, concept, or intervention is still in development or testing. They primarily serve an optimization function: the goal is to continuously improve the evaluation object during its development or application. Continuous feedback of evaluation results into practice is beneficial, enabling improvements to be implemented and tested through multiple feedback loops [38].

Qualitative methods play an important role in the context of formative evaluations. They enable differentiated capture of experiences, assessments, pros and cons, and concrete change requests from evaluation participants and users [38]. For evaluating the NuDaK framework, this approach is appropriate because the framework is still in the testing phase and requires continuous improvements through iterative feedback loops.

Setting

The study was conducted in collaboration with a large acute care hospital in Austria and the software company that provides the electronic nursing documentation. Together with the stakeholders, we selected a surgical ward to pilot the NuDaK framework.



The stakeholders involved in the project were systematically selected through a stakeholder analysis.

In total, 15 stakeholders were identified. Ten active stakeholders participated directly in project activities (director of nursing, experts from the unit of nursing development, ward manager, a practical nurse at the piloting station, IT expert at the hospital, staff member of the software company, and expert in data security and quality management). Five passive stakeholders (executive management, IT business management, and IT requirements and implementation management) supported strategic decision-making and were regularly informed about progress but did not participate in the planned project activities.

Study Flow

The pilot implementation followed a detailed project plan aligned with the 4 aspects of the NuDaK framework. Overall project management was led by the principal researcher, who also served as the project leader. On the clinical side, a designated nurse representative served as the primary point of contact and coordinated all on-site activities. In addition, the software vendor assigned a dedicated project lead to support implementation and technical coordination. The study was conducted from February 2023 to June 2024 and comprised 6 phases: a kick-off phase (February 2023) for initial training and framework introduction; 4 piloting steps corresponding to NuDaK implementation steps 1 to 4, with final evaluation workshops; and project closure (June 2024) for final evaluation. Figure 2 outlines the evaluation timeline within the piloting steps.

Figure 2. NuDaK framework evaluation activities within the piloting steps.

Outcome Measure

This study evaluated the NuDaK framework using 2 primary outcome measures: completeness and applicability.

Completeness addresses whether the framework covers all necessary aspects and activities comprehensively, ensuring there are no gaps in the intended scope. Applicability examines how well the framework fits the real health care environment, including its clarity, usability, and suitability for end users in practice.

The evaluation addressed these predefined criteria using the following guiding question, as presented in Table 1.

XSL•FO
RenderX

Table . Evaluation questions on completeness and applicability of the NuDaK framework.

Main evaluation question	Subquestions
Completeness evaluation	
Q1. Is the set of aspects covered in the NuDaK framework complete and sufficient?	• Are additional aspects or themes required to improve comprehensiveness?
Q2. Are the activities assigned to each NuDaK aspect logically connected?	• Do the activities follow a coherent and meaningful sequence?
Q3. Is each activity within the NuDaK framework feasible to perform in practice?	• Are temporal dependencies between activities clearly defined and logically structured?
Q4. Is each NuDaK framework activity feasible in practice, given the required resources and time?	• Does the framework link resource needs to specific aspects, activities, or methods? • Is the time required for each step realistic and proportionate to available resources?
Applicability evaluation	
Q5. To what extent is the NuDaK framework applicable in practice?	• Are the described aspects and activities understandable and logically structured?
Q6. How clear and comprehensible are the NuDaK framework's aspects and activities for end users?	• Can users easily interpret the purpose of each activity? • Are the expected outcomes of each activity clear? • Are ambiguities or overlaps present between framework components?
Q7. Are the methods and tools recommended within the NuDaK framework suitable for achieving the intended objectives?	• Do the recommended methods adequately support data reuse processes in the nursing context?
Q8. Are the designated expert roles appropriately aligned with the respective NuDaK framework activities?	• Do responsibilities and competencies correspond to the requirements of each activity?

Data Collection

Overview

We combined 3 complementary data collection methods (workshops, internal self-evaluation, and focus group interviews) to address all evaluation questions regarding completeness and applicability of the NuDaK framework. This multimethod approach enabled triangulation of findings and captured both external perspectives (workshops and focus group) and internal methodological reflections (self-evaluation).

Workshops (External Formative Evaluation)

Four workshops were conducted with actively involved project participants to evaluate the applicability of the methods applied in each step and to identify practical barriers, ambiguities, or missing components in the NuDaK framework.

Each workshop included 6 to 10 participants, comprising the director of nursing, ward manager, nursing staff of the piloting station, nursing representatives, IT experts, a staff member of the software company, and an expert in data security and quality management.

Participants were selected based on their active involvement in the piloting steps and their direct experience with NuDaK framework activities.

The workshop questions were adapted to align with the overarching evaluation questions from Table 1, with context-specific modifications for each piloting step.

For example:

- Is the BPMN (Business Process Model and Notation) modeling method suitable for visualizing real documentation processes on the ward?
- Are nursing staff able to use this visualization to assess processes on the ward for completeness and accuracy?
- Are the activities assigned to each NuDaK aspect logically connected and do they follow a coherent sequence?
- Is each activity feasible to perform in practice, given the available resources and time?
- Are the described aspects and activities understandable to end users?

All workshops were audio-recorded and supplemented with written workshop documentation (participant notes, process diagrams, and feedback sheets). Audio files were stored securely and transcribed for qualitative analysis.

Internal Self-Evaluation

Throughout the project, the researcher conducted a structured self-evaluation to assess whether the methods used achieved the goals of each specific aspect and activity of the NuDaK framework. This involved a continuous review process using the project implementation guidelines as a reference framework.

The project guidelines helped identify whether the planned NuDaK activities could be implemented effectively and whether they were applicable and suitable for achieving the goals of each specific aspect and activity. They also helped determine whether any activities were missing, whether they were applied

XSL•FO
RenderX

in the correct sequence, and whether the overall timeline was appropriate. Furthermore, the self-evaluation considered whether the active stakeholders involved in the project had sufficient competencies for their assigned tasks. The researcher maintained continuous self-evaluation notes throughout the study. These notes were stored and served as supplementary data for qualitative analysis.

Focus Group Interview (External Formative Evaluation)

The final online focus group interview (n=5) followed a semistructured guideline and was developed to (1) explore the conceptual understanding and perspectives on the secondary use of routine nursing data, (2) assess the applicability, comprehensibility, and practical relevance of the NuDaK framework, (3) explore challenges, barriers, and facilitating factors in implementing a data strategy for the secondary use of routine data, (4) critically reflect on the composition, roles, and contributions of the stakeholder group, and (5) explore the perceived institutional and organizational added value resulting from the project.

The focus group included 5 project participants (the director of nursing, an IT expert, a member of the software company, and 2 designated nursing representatives). The participants were selected based on their comprehensive involvement across all 4 piloting steps and their ability to provide synthesized perspectives on the framework's overall implementation.

The focus group interview was audio-recorded via the online platform and automatically transcribed.

Data Analysis

Data obtained from workshops and focus group interviews were audio-recorded and transcribed in summary form after each session.

We applied a deductive qualitative content analysis approach based on the 8 predefined evaluation questions (Q1-Q8) from Table 1. The coding process included initial coding based on the evaluation questions, and the analysis was supported by MAXQDA Analytics Pro 2022 (VERBI Software GmbH).

Findings from the internal self-evaluation were triangulated with external qualitative data from the workshops and focus group discussions to identify convergent and divergent assessments, identify refinement needs, and generate recommendations to optimize the NuDaK framework.

Ethical Considerations

This study was conducted in accordance with the standards laid out by the Research Committee for Scientific Ethical Questions. Research Committee for Scientific Ethical Questions is an independent body of the Tyrolean Private University UMIT that examines planned research projects that, due to legal provisions, do not fall under an ethics committee's jurisdiction.

Results

Overview

This section presents the results of the evaluation of the NuDaK framework (2022). Six deductive categories were developed to assess both its applicability and completeness. The categories include definitions and the corresponding evaluation questions, as described in the *Methods* section (see Table 2).

Table . Evaluation categories for completeness and applicability of the NuDaK framework.

Completeness	Applicability
Completeness of framework components (Q1)	Traceability of activities and comprehensibility for users (Q5 and Q6)
Structure, distinctness, and temporal logic of the framework components (Q2)	Suitability of methods and tools (Q7)
Feasibility of NuDaK framework activities in practice (Q3 and Q4)	Roles and responsibilities (Q8)

Completeness of the Framework Components (Q1)

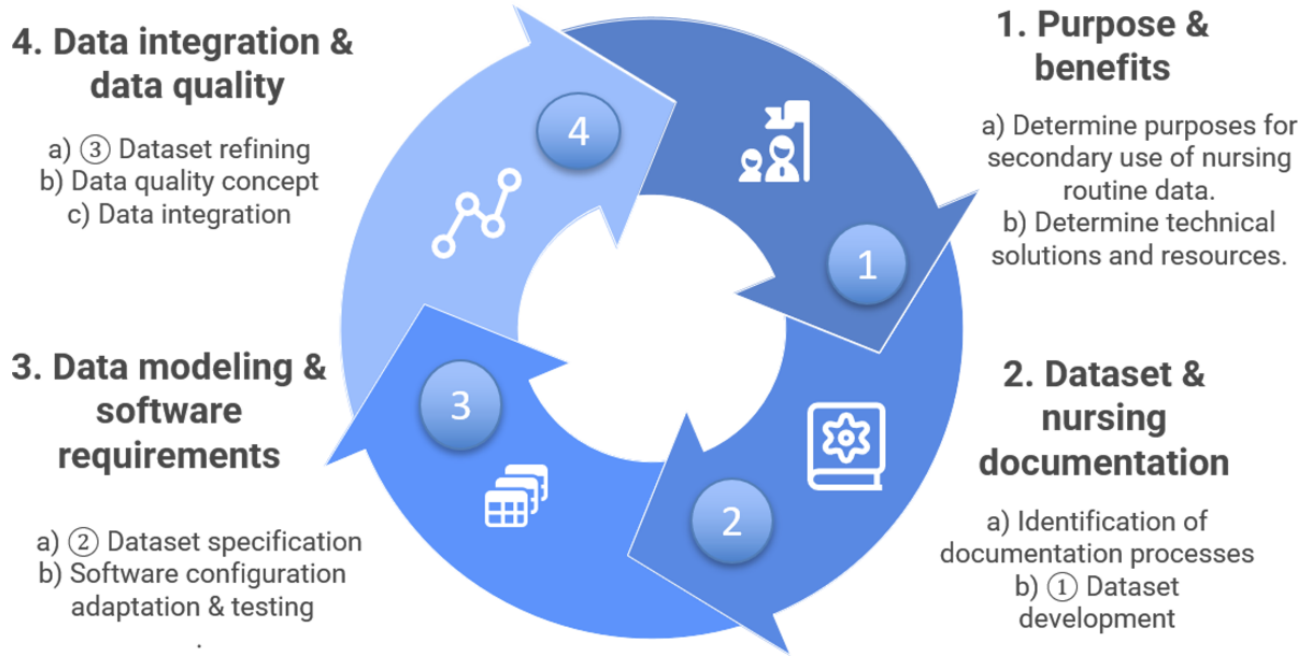
The pilot evaluation indicates that the NuDaK framework's core aspects "Purpose & Benefits," "Dataset & Nursing Documentation," "Data Modelling & Software Requirements," and "Data Integration & Data Quality," cover the essential domains required to plan and implement the secondary use of nursing data. Accordingly, the aspect set was generally perceived as sufficient at the conceptual level.

However, the pilot also showed that several framework-level components require more explicit specification to make the framework complete for practical use, such as (1) explicitly embedding a temporal dimension (phases 1 - 4), (2) defining interdisciplinary stakeholder involvement throughout the phases, and (3) specifying professional roles with role profiles and responsibilities.

In addition, the pilot revealed targeted content gaps within individual aspects. Within "Data Modelling & Software Requirements," an explicit documentation and adaptation concept emerged as necessary to guide systematic changes in the documentation system. Within "Data Integration & Data Quality," additional activities were required, including a strategy workshop to clarify key contextual conditions (eg, technical infrastructure, legal constraints, and staffing) and the development of a data quality concept.

Finally, as a cross-cutting addition, the pilot highlighted the importance of a standalone, iterative information model that is explicitly integrated into the framework. Such a model supports both top-down and bottom-up refinement across dataset development, specification, and revision (see Multimedia Appendix 1). Early and continuous involvement of an interdisciplinary group was considered essential for defining shared objectives and balancing diverging interests. A

XSL•FO
RenderX



combination of direct nursing practice, nursing management, nursing informatics/nursing development, and local IT was considered effective.

Structure, Distinctness, and Temporal Logic of the Framework Components (Q2)

The evaluation showed that the original linear and sequential representation of activities did not align well with practical requirements. Instead, it revealed a circular logic with recurring activities across multiple phases. Consequently, activities should not only be arranged in a single sequence but must also be distinguished by their temporal nature as either chronological key activities or iterative, cross-aspect activities.

In response, the revised NuDaK framework adopts a circular design comprising 4 phases, each assigned to an overarching aspect (see Figure 3). This structure makes iterative loops explicit and distinguishes between phase-specific key activities and recurring, cross-aspect activities.

Figure 3. NuDaK nursing data strategy framework 2025, representing aspects and activities.

Moreover, the pilot revealed that some activities must be scheduled more precisely to avoid late rework and loss of focus. A strategy workshop to clarify technical infrastructure, legal constraints, and human resources should be anchored early and assigned to “Purpose & Benefits” (phase 1). Likewise, a strategy for data querying and downstream processing should ideally be available by the end of phase 2 or, at the latest, at the beginning of phase 3. Finally, participants indicated that, in phase 4, the purpose and objectives of secondary use often require renewed clarification to maintain the intended focus of the data analysis.

Feasibility in Practice in Terms of Resources and Time (Q3 and Q4)

Overall, the evaluation suggests that the NuDaK framework activities are feasible to perform in practice. Nevertheless, feasibility is conditional on (1) an adequate time budget, (2) clearly assigned responsibilities, (3) access to relevant expertise, and (4) sufficient technical infrastructure.

At the activity level, participants described workshops, process modeling, and iterative concept development (eg, defining data purposes, modeling documentation processes, and specifying data quality criteria) as realistic and implementable when key stakeholders can be convened. In contrast, activities linked to implementation in the documentation system were perceived as particularly resource-intensive, especially testing adaptations of new applications, coordinating change management, and training staff after adaptations (including practical materials such as handouts and explicit clarification of “who does what”).

Participants repeatedly reported that more time would have been beneficial, indicating that the planned time requirements of individual steps were perceived as tight in the pilot setting. In addition, the pilot underscored that sustainable continuation of a data strategy requires building organizational know-how over time, for example, through collaborations and structured training pathways (eg, university partnerships).

Taken together, the findings support making resource requirements and time demands more explicit within the framework by indicating resource-critical activities (eg, documentation system adaptations, data harmonization, and training) and by providing more realistic time estimates or planning guidance for key steps.

Traceability of Activities and Comprehensibility for Users (Q5 and Q6)

The evaluation showed that the NuDaK framework is generally applicable in practice. Participants reported that they could independently develop a data strategy based on the framework, provided that the data purpose and supporting roles are defined early within an interdisciplinary setting.

Comprehensibility and traceability increased throughout the pilot project. However, at the outset, the framework was

XSL•FO
RenderX

perceived as insufficiently concrete. Participants specifically noted that additional start-up input would have been helpful, including concrete examples and use cases.

A conceptual hurdle regarding the meaning of secondary use and the logic of routine data became apparent. Participants described the question "How can we benefit from the data and analyses?" as difficult to answer, and clarification of what secondary use entails emerged only during discussion. In addition, nursing managers and nursing developers often framed the topic in documentation-oriented terms and immediately sought documentation changes to enable analyses, which can conflict with the logic of routine data. These observations indicate that early alignment and clarification, supported by examples, are required from the outset.

Suitability of Methods and Tools (Q7)

Overall, the results suggest that the methods and tools recommended in the NuDaK framework are suitable for achieving the intended objectives and enabling the secondary use of nursing data. Workshops were described as central platforms for strategic decision-making, and audio recording was highlighted as a helpful documentation instrument to secure outcomes.

At the same time, the pilot indicated that methods often need to be adapted in application and, in some cases, applied repeatedly to achieve the desired results. Within "Dataset & Nursing Documentation," developing scenarios for documentation processes, BPMN modeling, and evaluation with nursing practitioners were perceived as effective and goal-oriented. BPMN modeling was considered particularly useful because it is understandable to nursing staff and provides a transparent basis for identifying software-related adaptation needs and relevant data sources.

For "Data Integration & Data Quality," the 2-step approach to developing the data quality concept was considered appropriate: selecting suitable quality dimensions from the literature (eg, completeness, concordance, plausibility, and timeliness) and subsequently operationalizing and validating them in a workshop with IT and nursing experts using practical examples and testing criteria. Moreover, data preparation requires continuous feedback from nursing staff, and harmonizing concepts (data objects) into a uniform data format is indispensable for larger datasets. In summary, the recommended methods most effectively support the intended objectives when applied iteratively and complemented by concrete examples/use cases and appropriate documentation instruments (eg, audio recordings).

Roles and Responsibilities (Q8)

The pilot implementation clearly demonstrated that professional roles, competencies, and responsibilities must be explicitly embedded within the framework, as they are essential for carrying out the activities.

Nursing informatics expertise emerged as central. Implementing a data strategy requires strong competencies in nursing informatics, and nursing informatics specialists should assume the lead and coordinating role. In addition, competencies in data science/data mining and data warehousing, as well as knowledge of programming languages and databases, must be combined with nursing/medical domain knowledge to interpret data correctly and understand nursing processes.

The designation of an independent data administrator role was identified as advantageous to ensure that data are available in the required format and granularity, particularly in phase 3 of implementation. Furthermore, topic-specific nursing expertise in the early phases (eg, a "pain nurse") was considered essential to align activities with nursing requirements.

To support practical implementation, responsibilities should be conceptualized not only as individual roles but also as clearly defined interdisciplinary expert groups for each phase to enable joint strategic alignment, holistic requirements consideration, and the balancing of diverging interests.

NuDaK Framework 2025: A Data Strategy to Reuse Nursing RWD

The evaluation of the applicability and completeness of the NuDaK Framework 2022 provided essential insights for its further development and refinement. Building on these findings, the framework was systematically adapted. In the following section, we present a short version of the updated NuDaK Framework 2025. A comprehensive description of the NuDaK Framework 2025, including detailed activities, methods, and role descriptions, is provided in Multimedia Appendix 1.

Major changes to the updated NuDaK framework comprise a clear temporal structure (phases 1 - 4). Furthermore, it is now conceptualized as a combination of chronological key activities and iterative, cross-aspect activities. In addition, the framework was strengthened by defining interdisciplinary stakeholder involvement, specifying professional roles, responsibilities, and competencies, and highlighting key prerequisites for feasibility.

Alongside this, a standalone, iterative information model was integrated to continuously improve the dataset (see Multimedia Appendix 1).

The NuDaK framework 2025 is a practice-oriented data strategy that structures the secondary use of routinely collected nursing data into 4 temporal phases and 4 corresponding aspects: (1) Purpose & Benefits, (2) Dataset & Nursing Documentation, (3) Data Modeling & Software Requirements, and (4) Data Integration & Data Quality (Figure 3). In addition to these aspects, the framework specifies activities and associated methods. Across all phases and aspects, implementation is enabled by defined professional roles and responsibilities (eg, nursing informatics specialist, IT professionals, data administrator, ward management, and domain experts) that support the implementation of NuDaK.

In *Phase 1 (Purpose & Benefits*), organizations define the aims, expected benefits, and scope of secondary data use. Objectives are established through interprofessional consensus workshops and aligned with feasibility considerations (eg, data processing location, technical infrastructure, data science competencies, and regulatory constraints). Key deliverables are a purpose statement and an agreed analytical scope.

XSL•FO
RenderX

Phase 2 (Dataset & Nursing Documentation) focuses on understanding documentation practices and deriving a robust dataset. Documentation workflows are captured using scenario-based analysis and process modeling (eg, BPMN), followed by expert review. In parallel, the dataset is developed as the first stage ① of the *information model* using a top-down approach (a literature-informed theoretical dataset), refined against real documentation through use cases, and validated by domain experts.

In *Phase 3 (Data Modeling & Software Requirements)*, the dataset is formally specified (information model stage ② [dataset specification]) by standardizing elements, defining attributes and permissible values, and adding missing fields as required. These specifications are translated into software requirements, followed by system configuration, user-centered adaptation, training support, and a structured testing period to ensure applicability and completeness of data capture.

Phase 4 (Data Integration & Data Quality) operationalizes information model stage ③ (dataset refinement) and establishes prerequisites for valid analyses. Iterative test queries are used to verify availability, formats, value ranges, and data types across sources. A data quality concept is developed by selecting core quality dimensions (eg, completeness, concordance, plausibility, and currency) and defining practical evaluation examples and validation procedures with clinical and technical experts. Finally, data integration consolidates validated data into a unified, analysis-ready structure while ensuring traceability, governance, and alignment with refined research questions. Further details are provided in Multimedia Appendix 1.

Discussion

Principal Results

This feasibility study evaluated the completeness and applicability of the NuDaK framework (2022) in a real-world nursing setting and used the findings to refine the framework into NuDaK 2025. Overall, the core set of aspects was confirmed as sufficient to cover key domains required for the secondary use of nursing routine data. However, NuDaK implementation showed that a linear representation does not reflect the iterative character of data strategy work in clinical environments.

Consequently, NuDaK 2025 now adopts a circular structure with 4 temporal phases and makes feedback loops explicit. In addition, the pilot indicated the need to (1) embed an explicit temporal dimension (phases 1 - 4), (2) formalize professional roles and responsibilities, and (3) introduce a standalone, iterative information model spanning dataset development, specification, and refinement across phases 2 to 4. Taken together, these refinements indicate that feasibility in this context depends not only on the content of the framework, but also on its ability to reflect the actual workflow logic of clinical implementation.

Results in Relation to Other Frameworks

NuDaK 2025 offers a nursing-specific, end-to-end strategy that connects purpose definition, dataset and documentation work, technical specification and software adaptation, and, finally, data integration and quality assurance. This distinguishes it from frameworks that address only selected parts of the reuse pathway.

The SPIRIT framework offers valuable guidance for organizational planning and system-level preparation, but it is not tailored to nursing purposes and does not operationalize the pathway from documentation to a reusable nursing dataset in the same level of detail [16].

Likewise, the Health Data Quality Framework is for assessing and visualizing EHR quality but does not provide an integrated life cycle strategy for the secondary use of nursing data that includes documentation processes and software implementation [33]. Nursing data mining approaches, including predictive modeling, focus more strongly on analytic reuse and less comprehensively on the upstream prerequisites, such as governance, integration, and quality management, that are needed before advanced analysis can take place [34].

Against this background, NuDaK extends existing approaches by combining strategic, organizational, technical, and methodological elements within one nursing-specific framework.

It covers the entire process from nursing documentation to a usable dataset for nursing analytics in a practical, step-by-step manner.

Methodological Implications

This exploratory study also shows methodological implications for the development and evaluation of complex frameworks in nursing informatics. First, it shows that formative feasibility work can reveal structural requirements that may not be fully visible at the conceptual design stage, especially when the framework is tested in real clinical practice. Second, the findings suggest that framework completeness should be interpreted not only as coverage of content domains but also as clarity of sequence, timing, roles, and feedback mechanisms. Third, the study illustrates the value of combining external qualitative evaluation with internal self-evaluation because these perspectives complement one another and help identify both practical barriers and areas for refinement.

Meaning and Generalizability

NuDaK 2025 provides a structured pathway for health care organizations and informatics specialists to establish the secondary use of routine nursing data. In particular, it can be used by nursing managers, hospital directors, or health informatics experts to plan, build, and implement the use of routine nursing data to improve nursing practice and support nursing research.

Its practical relevance lies in addressing common barriers that limit the reuse of nursing data. NuDaK particularly addresses insufficient standardization, variable data quality, and missing governance across the documentation-to-dataset pathway.

By aligning technical specification, software adaptation, and data quality assurance with nursing workflows, NuDaK can support robust analyses of large nursing datasets and thereby strengthen nursing quality management and evidence generation.

XSL•FO
RenderX

In the longer term, it may also contribute to establishing the data prerequisites for advanced analytics and AI-related applications. However, the implementation of such downstream applications requires additional technical, organizational, and methodological work beyond the scope of the present feasibility study. Given that AI applications in nursing rely on standardized, complete, and high-quality datasets, NuDaK may provide a relevant methodological foundation [10].

Overall, NuDaK 2025 should be understood as a strategy framework that structures the secondary use of routinely collected nursing data for quality improvement, research, and future analytic development.

Strengths and Limitations

A key strength of this feasibility study is that NuDaK was evaluated in a real clinical nursing setting and across multiple implementation phases, which allowed practical barriers and refinement needs to emerge from actual use rather than from theoretical reflection alone. The combination of workshops, focus group data, and internal self-evaluation also provided complementary perspectives on the same framework.

This study has several limitations. It was conducted in a single hospital ward, so transferability to other organizations with different workflows, documentation systems, or nursing terminologies is limited. In addition, the findings are based on qualitative perceptions and researcher self-evaluation rather than objective outcome measures, so they should be interpreted as exploratory. Future studies should therefore examine NuDaK in additional settings and complement qualitative findings with more objective implementation and outcome data.

Conclusions

Building on the need to better leverage routinely collected nursing documentation data, we developed the NuDaK framework as a practical guide for health organizations and research teams. Refined through a feasibility study in a real-world nursing setting, NuDaK now offers a nursing-specific, end-to-end data strategy across 4 phases, with explicit feedback loops, defined professional roles, and an iterative information model. The present feasibility study supports the conceptual refinement of the framework.

However, several issues remain only partially resolved. Further research is needed to evaluate the performance and transferability of the framework across heterogeneous institutions with different documentation systems, governance arrangements, vendors, and levels of digital maturity. Multisite studies are also needed to examine data harmonization and interoperability requirements across settings and software solutions. Future studies should also validate NuDaK through concrete nursing use cases and exemplar analyses while assessing its longitudinal sustainability and impact in routine practice.

Acknowledgments

The authors gratefully acknowledge all experts and practice partners for their valuable feedback and contributions to piloting and evaluating the NuDaK framework. We also thank the participating health care organization and the software company for their support in the feasibility study and technical implementation.

Generative AI Use

During the preparation and revision of this manuscript, the authors used ChatGPT (GPT-6.1 Sol; OpenAI) to support language editing, improve clarity and readability, and refine the structure and wording of selected passages. Napkin AI was used to support the graphical visualization of concepts. Perplexity AI and Elicit were used to assist with literature searches and the identification of relevant scientific publications. All AI-assisted outputs were critically reviewed and verified by the authors, who take full responsibility for the accuracy, originality, and integrity of the manuscript, including all references and citations.

Abstract

Background: Socially assistive robots are increasingly explored in health care, but evidence from routine pediatric outpatient settings remains limited.

Objective: This study examined how contextual support and human facilitation shaped visitor interaction with the Temi V3 robot and which sociotechnical conditions were associated with practical acceptance according to staff.

Methods: A mixed methods pilot combined structured behavioral observation across baseline, poster support, and staff facilitation conditions with 4 staff focus group interviews. The observation unit was a visitor passage through the lobby zone; the qualitative sample comprised 12 staff members with direct exposure to the robot. Quantitative indicators were analyzed descriptively, and staff interviews underwent deductive-inductive qualitative content analysis.

Results: In total, 675 visitor passages (children: n=398, 59% and adults: n=277, 41%) were recorded (baseline: n=257; poster support: n=160; and staff facilitation: n=258). Looking at the robot increased from 8 (3.1%) passages at baseline to 30 (18.8%) with poster support and 80 (31%) with staff facilitation. Screen or app use increased from 2 (0.8%) passages at baseline to 4 (2.5%) with poster support and 14 (5.4%) with staff facilitation. Observer notes indicated stronger visible responsiveness among children, although age category was not linked to individual behavior codes. Staff emphasized role clarity, child and family value, human mediation, functional reliability, multilingual content, and organizational ownership.

Conclusions: Observed visitor interaction was higher with poster support and staff facilitation than at baseline. These descriptive findings and staff perceptions informed a provisional 4-domain framework comprising role clarity, interaction affordance, social mediation, and organizational embedding. The framework identifies potential implementation priorities; visitors' own experiences and acceptance require direct assessment.

socially assistive robots; human-robot interaction; hospital navigation; mixed methods; technology acceptance

Introduction

Background

Socially assistive robots (SARs) are designed to support people through social interaction without providing direct physical assistance [1,2]. In health care, they have been explored as guides, companions, educators, telepresence platforms, and communication mediators [3-5]. Hospitals are especially relevant settings because they combine logistical complexity with emotional strain, repeated information needs, and heavy staff workload [3,6,7].

Pediatric outpatient environments add a further layer of complexity. Children often face uncertainty, waiting, unfamiliar spaces, and procedure-related stress, while parents must simultaneously manage navigation, appointments, and the child's emotional state. Prior reviews suggest that social robots can support children's well-being during medical treatment through distraction, engagement, and emotionally lighter interaction, but the evidence remains heterogeneous and strongly context dependent [8,9]. Hospital human-robot interaction (HRI)

XSL•FO
RenderX

reviews likewise show that pediatric settings are promising, while many studies remain short-term, small-scale, or conducted under controlled conditions instead of routine clinical conditions [3,7].

Implementation is an additional challenge. Health care robot adoption is rarely determined by technical capability alone. Acceptance depends on whether users understand what the robot is for; whether it fits work processes; whether it is easy to use; and whether organizations provide the training, maintenance, and responsibility structures needed for sustained use [10-12]. Recent European survey evidence also suggests that public support for SARs in health care is conditional. People appear more comfortable with bounded assistive roles, such as information provision and guidance, than with higher-stakes gatekeeping or quasi-clinical decision roles, and privacy remains a recurring concern [13].

Study Context

The present study examined a Temi V3 robot in the second-floor outpatient area of Tallinn Children's Hospital in Tallinn, Estonia. The Temi V3 is a mobile platform with screen-based interaction, speech output, and navigation capabilities [14]. The robot was introduced as a public-facing assistive technology for wayfinding, simple informational support, and child-friendly engagement during waiting. Related earlier work by the research team examined scenarios for telepresence robots in health care [15]; the present manuscript reports a separate 2025 field pilot focused on a SAR in a pediatric outpatient setting.

Theoretical Background

SARs in Hospitals and Pediatric Care

The health care robotics literature includes several overlapping categories, including service robots, social robots, SARs, companion robots, and telepresence robots [2,4,5]. The term SAR is the most relevant term for the robot used in the study (Temi V3), as it was not intended to perform invasive or physically assistive clinical work. Its intended value lay in communication, guidance, and emotionally supportive interaction, which aligns with assistance through social engagement [1].

Systematic reviews show that hospital SARs have been implemented in reception, wayfinding, education, rehabilitation, companionship, telepresence, and administrative support [3,4,7]. Broader surveys similarly suggest that near-term adoption is most plausible in bounded domains such as communication, navigation, logistics, telepresence, and patient-facing service functions, where robots can add value without assuming clinical agency [6]. Many hospital robots therefore occupy an intermediate position: they are neither entertainment devices nor autonomous care professionals, but hybrid systems whose usefulness depends on how well they extend existing human service processes.

In pediatric care, published work has frequently focused on play, distraction, procedure support, emotional comfort, and engagement during waiting or treatment. Moerman et al [8] concluded that social robots may support children's well-being, especially by reducing distress and stimulating positive engagement, while also noting that much of the evidence comes from small or highly contextual studies. Kabacińska et al [9] found that children, parents, and health care providers may all see value in pediatric hospital robots, while emphasizing workflow fit, co-design, and responsible implementation.

The field nevertheless remains uneven. Reviews report positive interaction outcomes alongside recurring friction points, including technical unreliability, overestimated autonomy, narrow interaction repertoires, poor personalization, and weak integration into the social context of care [5,7,10]. A robot's observed use in a hospital cannot therefore be understood as a property of the machine alone. It also reflects the information environment, user expectations, staff mediation, physical setting, and local routines.

Acceptance and Implementation of Health Care Robots

Technology acceptance research offers a useful starting point. The technology acceptance model (TAM) identifies perceived usefulness and perceived ease of use as central drivers of adoption [16]. The UTAUT (unified theory of acceptance and use of technology) adds social influence and facilitating conditions, which are particularly relevant when technologies are introduced through organizational channels [17]. Staff and visitors assess technical capability together with usefulness, understandability, approachability, and visible social endorsement.

For social robots, the Almere model extends acceptance thinking by incorporating trust, enjoyment, social presence, and anxiety [18]. Although developed in work with older adults, its broader insight is relevant here: acceptance of a social agent reflects both functional evaluation and the felt quality of interaction. In pediatric contexts, playful engagement, attention redirection, and perceived warmth may matter alongside instrumental usefulness [8,9].

Acceptance models alone do not capture implementation fully. Reviews of SARs in health and social care identify insufficient training, unclear role boundaries, additional workload, technical unreliability, privacy and safety concerns, weak customization, and the absence of local champions or maintenance structures as recurring barriers [10,11,19]. Stakeholder-oriented design studies similarly indicate that acceptability improves when robot functions are visibly useful, easy to understand, robust in busy environments, and aligned with actual care needs [11].

Acceptance is also multiactor. Children, parents, frontline nurses, administrative staff, technical staff, and managers may evaluate the same robot differently because they encounter different benefits, burdens, and risks. Early interest may coexist with reservations about accountability, privacy, maintenance, and role boundaries [10,13,19]. Qualitative work with nursing professionals likewise indicates that robots gain legitimacy when attached to concrete support tasks and when organizational conditions for integration are explicit [12,20].

Analytical Framework and Study Aim

Drawing these strands together, the study used 4 sensitizing domains: role clarity, interaction affordance, social mediation, and organizational embedding. Role clarity concerns whether

XSL•FO
RenderX

the robot has an obvious and locally meaningful purpose. Interaction affordance concerns whether visitors and staff can understand how to start, continue, benefit from, and recover from interaction. Social mediation concerns whether signage, demonstration, and visible endorsement reduce uncertainty and invite use. Organizational embedding concerns workflow, training, support, maintenance, content management, and responsibility. The 4 domains were developed as an author synthesis of TAM, UTAUT, the Almere model, and implementation evidence [10,11,16-20]. They guided deductive coding and mixed methods interpretation, while inductive analysis remained open to recurrent issues raised by staff. The framework is provisional and is not presented as a validated scale.

The aim of the study was to examine how contextual support shaped observable visitor interaction with Temi V3 and which sociotechnical conditions staff associated with its practical acceptance in pediatric outpatient care. The following research questions (RQs) guided the study:

- RQ1: How did the 4 observed interaction indicators (looking at the robot, approaching it, touching it, and using the robot's screen or app) vary across baseline, poster support, and staff facilitation conditions?
- RQ2: Which sociotechnical factors did hospital staff identify as enabling or constraining practical acceptance and integration of the robot?

Methods

Research Design and Integration

The study used a mixed methods pilot design with separate quantitative and qualitative analyses and convergent interpretation [21]. The quantitative strand examined spontaneous visitor interaction with the robot under 3 sequential implementation conditions. The qualitative strand explored how staff perceived the robot's usefulness, limits, and implementation requirements through small focus group interviews. The strands were analyzed separately and then interpreted together to relate observable visitor behavior to staff perspectives on implementation, without treating staff accounts as evidence of visitors' own perceptions.

This design was selected because unobtrusive observation was needed to document what people actually did near the robot under routine hospital conditions, while interviews were needed to understand how staff interpreted the robot's role, usefulness, support burden, and fit with everyday work. The study did not link the 2 datasets at the person level. It used them as complementary evidence about immediate visitor uptake and organizational implementation.

The participant groups were intentionally different. The observation strand included naturalistic visitor passages, whereas the qualitative strand included employees with direct experience of using, observing, supporting, or coordinating the robot. Children, parents or guardians, and other adult visitors were not interviewed; claims about these groups are therefore limited to observed behavior and staff perceptions. RQ1 was addressed through condition-level behavior counts, observer-assigned age categories, and contemporaneous field notes, and RQ2 through staff interviews. Integration occurred after the separate analyses.

Setting and Robot

The study took place in the second-floor outpatient lobby at Tallinn Children's Hospital. Families in this area navigate several specialties and may encounter uncertainty about room locations, changing numbering systems, and waiting routines. The robot's intended public-facing functions included wayfinding, basic hospital information, and child-friendly engagement during waiting.

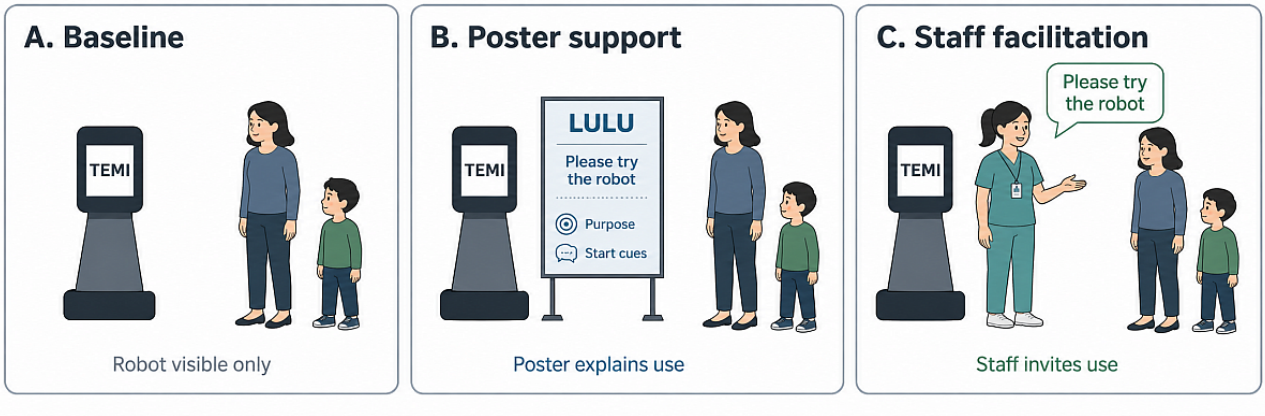
The robot's pilot interface combined hospital-specific and generic elements in the national language (Estonian). Mapped hospital destinations and selected hospital information were available alongside generic Temi content, including news and simple entertainment. The robot's hardware, mapped destinations, screen content, and physical location remained unchanged across the 3 observation conditions. The experiment's conditions differed only in the external contextual support provided.

Quantitative Strand: Structured Behavioral Observation

Participants, Sampling, and Eligibility

The unit of analysis was a visitor passage through a predefined lobby observation zone during the scheduled observation periods. Consecutive passages were included when a person entered the zone within an observation window. Passages outside the zone or outside the scheduled period were excluded. No further demographic or behavioral eligibility criteria were applied because the purpose was to document naturalistic visitor flow. Observation was kept nonintrusive and anonymous, so repeat passages by the same person could not be identified or excluded. The reported totals represent passages and cannot be interpreted as counts of unique visitors. Observers assigned a descriptive age category of child or adult. Age category was not linked to each individual behavior code in the aggregated dataset. Age-related findings are therefore based on phase-level counts and field notes, and no statistical comparison of child and adult engagement rates was possible.

Implementation Conditions and Observation Protocol



Observation occurred under 3 sequential conditions (Figure 1): baseline (May 22 - 23, 2025), poster support (June 5 - 6, 2025), and staff facilitation (June 12 - 13, 2025). At baseline, the robot was available without added contextual support. In the poster condition, a sign introduced the robot's name, purpose, and simple interaction cues. In the staff facilitation condition, a hospital intern stood near the robot and verbally invited visitors to interact.

Two observers monitored the lobby using a predefined protocol. One focused on entries and exits, while the other recorded visible interaction near the robot. Engagement was operationalized as 4 progressive but separately tallied indicators: looking at the robot, approaching it, touching it, and using the screen or app. A passage could contribute to more than 1 indicator, so the indicators were not mutually exclusive. The 4

XSL•FO
RenderX

indicators were retained as separate outcomes and were not averaged across conditions.

Figure 1. Three sequential implementation conditions in the pediatric outpatient lobby. The robot and its location remained unchanged; only the contextual support differed.

Quantitative Analysis

Frequencies and percentages were calculated separately for each behavior indicator and condition. As an additional descriptive summary, the 4 indicator counts were summed within each condition, divided by the number of visitor passages in that condition, and multiplied by 100. This summary represents recorded indicators per 100 passages, not the percentage of passages with any interaction or a measure of acceptance, because the indicators may overlap. The analysis was descriptive because the field conditions were sequential, nonrandomized, and conducted on different dates. No inferential tests or *P* values were calculated. The quantitative results were compared with staff themes during mixed methods interpretation.

Qualitative Strand: Staff Focus Groups

Participants and Sampling

The qualitative strand comprised 12 health care professionals interviewed in 4 small focus group sessions. Sampling was purposive and criterion based. Inclusion required employment at Tallinn Children's Hospital and direct exposure to the robot through use, observation, support, or deployment-related coordination. The available role information represented frontline clinical and nursing perspectives as well as coordination-level and senior organizational perspectives. Staff without direct robot exposure, hospital visitors, children, and parents or guardians were excluded.

To protect employees from possible deductive identification within the relatively small hospital workforce, detailed demographic data, including exact age, gender, tenure, and job title, were not collected. The manuscript therefore reports only the available broad role-level information. The limited demographic detail is acknowledged as a study limitation, and a structured summary of the available sample characteristics is provided in Multimedia Appendix 1.

Interview Procedure and Analysis

The interview guide covered opportunities for robot use, factors supporting and hindering use, suitable functions in interaction with children and parents, and organizational needs connected to implementation. Participation was voluntary. Sessions were audio-recorded, transcribed using automated speech recognition, manually corrected, deidentified, and stored on institutional infrastructure for the approved research purpose.

A deductive-inductive qualitative content analysis was used [22,23]. Deductive coding drew on the interview topics and the 4 sensitizing domains. Inductive coding remained open to recurrent issues raised by participants. Codes and themes were reviewed iteratively in line with established qualitative analysis guidance [24]. The focused sample was considered information rich for exploratory analysis because all participants had direct exposure to the robot and its organizational setting [25]. A supplementary overview of the resulting themes is provided in Multimedia Appendix 1.

Mixed Methods Integration

After separate analysis, condition-level observation patterns were compared with staff perceptions of usefulness, interaction difficulty, human mediation, and organizational support. This comparison informed the provisional 4-domain framework presented in the Results section. The datasets involved different participant groups and were not linked at the person level; staff accounts were used to contextualize observed patterns, not to establish visitors' own perceptions or reasons for interacting.

Ethical Considerations

The study comprised anonymous, noninvasive observation and voluntary staff interviews. Ethics approval for observation was granted by the Tallinn Children's Hospital Research Ethics Committee (TCH/2025-01), and the interview component was reviewed by Tallinn University of Technology's Academic Ethics Research Committee. Because observation involved no recordings or identifiable personal data, individual consent was waived for the public space observation. Staff participants provided informed consent. Interview recordings and transcripts were stored securely, and the manuscript reports only aggregated observations and anonymized themes. All procedures complied with the General Data Protection Regulation (European Union 2016/679).

XSL•FO
RenderX

Results

Visitor Engagement Across the 3 Field Conditions

Across the 3 observation phases, 675 visitor passages were recorded, comprising 398 child and 277 adult passages. Each of the 4 separately recorded behavior indicators increased from baseline to poster support and again to staff facilitation (Table 1). The sums of the 4 indicator counts were 14, 52, and 156, respectively, corresponding to 5.4, 32.5, and 60.5 recorded indicators per 100 passages. These descriptive summaries include overlapping behaviors and are not percentages of passages with any interaction.

Table . Structured observation results by implementation condition, with a descriptive sum of overlapping indicator counts[a].

Condition	Looked, n (%)	Approached, n (%)	Touched, n (%)	Screen or app use, n (%)	Indicator sum[b], n (per 100 passages)
Baseline (n=257)[c]	8 (3.1)	2 (0.8)	2 (0.8)	2 (0.8)	14 (5.4)
Poster support (n=160)[d]	30 (18.8)	12 (7.5)	6 (3.8)	4 (2.5)	52 (32.5)
Staff facilitation (n=258)[e]	80 (31.0)	44 (17.1)	18 (7.0)	14 (5.4)	156 (60.5)

[a]Counts represent visitor passages, not confirmed unique individuals.

[b]The final column sums the 4 overlapping indicator counts within each condition. Values in parentheses in this column are counts per 100 passages. Because a single passage can contribute to multiple indicators, the sums do not represent distinct interaction episodes, passages with any interaction, or unique visitors.

[c]Includes 108 child and 149 adult passages.

[d]Includes 120 child and 40 adult passages.

[e]Includes 170 child and 88 adult passages.

In the baseline phase (n=257), the robot was largely ignored. Occasional automatic voice output did not translate into sustained use. Looking was recorded for 8 (3.1%) passages, while approaching, touching, and screen or app use were each recorded for 2 (0.8%) passages.

When the poster was added, visible interaction increased (n=160). Looking was recorded for 30 (18.8%) passages, approaching for 12 (7.5%) passages, touching for 6 (3.8%) passages, and screen or app use for 4 (2.5%) passages. The sign provided the robot's name, purpose, and interaction cues without changing its technical capabilities; whether visitors found these cues clearer or more useful was not assessed.

The highest counts occurred when a staff mediator stood near the robot and explicitly invited use (n=258). Looking was recorded for 80 (31.0%) passages, approaching for 44 (17.1%) passages, touching for 18 (7.0%) passages, and screen or app use for 14 (5.4%) passages. In descriptive terms, the phases represented progressively stronger levels of contextual and social support.

Contemporaneous field notes indicated that children were the most visibly responsive users in each phase, initiating contact through looking, approaching, touching, or play, while adults more often engaged in a supervisory or instrumental manner, for example, by watching a child interact or asking what the robot was for. Because age category was not linked to person-level behavior codes, these observations do not establish age-specific engagement rates and are not presented as a statistical comparison.

Staff Perspectives on Robot Use and Adoption

Staff Participant Background

The 4 focus groups included 12 staff members with direct exposure to the robot and represented both frontline clinical and organizational perspectives. The available role-level information is summarized in Multimedia Appendix 1. The absence of exact age, gender, tenure, and job title counts is considered when interpreting the transferability of the qualitative findings.

The interviews produced 5 interrelated themes. Multimedia Appendix 1 provides a compact overview; the main findings and illustrative quotations are presented below.

The Robot Was Accepted When Its Role Was Concrete and Visible

Staff were generally positive about the robot and did not describe strong resistance to its presence. Staff described a concrete and visible function as important for the robot's acceptance. The most frequently mentioned use case was wayfinding: helping families locate rooms, navigate the outpatient floor, or reduce confusion related to changing numbering systems and unfamiliar layouts. One participant explained:

> *If you have two children with you and you are looking for a four-digit room number, that is quite difficult for the parent…for the parent it is easier, for the child it is fun, so it is a win-win.* [P11]

Another participant described the robot as a practical alternative when staff could not leave their own work area:

> *When someone asks me where room A2071 is, I have no idea. Then I say, let's look at Lulu, and they*

XSL•FO
RenderX

disappear with the robot. I do not have to run with them myself. [P12]

Several participants contrasted this concrete usefulness with a more diffuse sense that the robot was present but not yet integrated. As one nurse put it:

For me it is actually still a bit unfamiliar. [P3]

Child Engagement Created Indirect Value for Parents and Staff

Participants consistently described children as drawn to the robot's movement, voice, and games. Even when parents were initially reserved, children often initiated contact, and parents then followed. One participant described the robot as "something very interesting" for children and added:

The child's attention goes there, not, for example, to the procedure. [P5]

Another described a similar impression:

For a moment they forget. [P4]

Staff framed the benefit as indirect as well as direct: engaging the child could make waiting easier for parents and reduce some low-level interaction burden for staff. These accounts describe perceived value; the study did not directly measure anxiety, distraction, or satisfaction.

Human Mediation and Local Prompting Were Critical

Staff accounts were consistent with the higher interaction counts observed in the staff facilitation condition. Staff said the robot was used more when someone invited families to try it, explained what it could do, or modeled its use. A coordination-level participant stated:

When there was a person next to it, inviting people to use it, then it was used more. [P2]

The same participant identified the practical constraint:

There was no resource to put anyone next to it to introduce it. [P2]

Frontline staff described a similar need from another angle. One nurse noted:

Medical staff do not guide Lulu use. [P3]

Another participant preferred a dedicated introduction:

There is a specific time, no one interrupts, and then you know exactly. [P5]

Staff perceived invitations and demonstrations as helpful for initiating interaction. Visitors' own reasons for engaging or not engaging were not assessed.

Limited Functionality Constrained Broader Acceptance

Although participants valued the idea of the robot, they also identified practical limitations. These included slow movement, charging and troubleshooting problems, unclear audibility, uneven content quality, and the need for multilingual support. One participant summarized the technical issues:

More speed. Sometimes it does not charge. [P4]

Another suggested that the robot display a support contact when problems occurred [P6]. Content was also a recurring issue. A senior participant argued:

I would remove the news. No one reads the news, children do not want to read them, and parents mostly watch the children play. [P12]

The participant proposed short, relevant "tips and tricks for parents" instead. A nurse noted that many visitors were Russian speakers while the device did not support Russian-language interaction [P3]. Positive attitudes therefore did not remove routine usability requirements.

Sustainable Use Required Organizational Ownership

A recurring issue was responsibility. Staff did not always know whom to contact when the robot malfunctioned, who could update its content, or who was expected to coordinate its place in daily work. One participant stated:

We need to choose Lulu's owner. [P12]

They added that if the hospital became the owner, responsibility should be assigned within the hospital. Another participant emphasized staff capacity:

The main problem here is time resource…people do not do it because they simply do not have the time. [P2]

Participants were open to broader use and viewed local responsibility for support, updates, and integration as important to its implementation.

Integrated Interpretation and Provisional Framework

Observed indicator counts were higher with poster support and highest with staff facilitation. Staff accounts were consistent with the potential importance of clear functions and human prompting but did not establish why visitors interacted or whether they experienced less uncertainty. The strands provide complementary evidence about observable behavior and staff perceptions of implementation, rather than direct confirmation of visitors' acceptance.

Field notes described children's visible responsiveness, while staff accounts identified perceived benefits and organizational needs. Together, these findings informed the provisional *mediated acceptance framework* in Table 2. The framework organizes possible links between visitor-facing support and staff-identified implementation conditions; it has not been validated against direct visitor feedback or sustained service outcomes.

XSL•FO
RenderX

Table . Provisional mediated acceptance framework linking observed visitor behavior with staff perceptions and proposed implementation priorities.

Domain	Evidence in this study	Proposed implementation priority
Role clarity	All 4 recorded indicators were higher with poster support than at baseline; staff emphasized wayfinding and room finding.	Define a bounded service task and make its purpose visible at the point of use
Interaction affordance	Screen or app use remained limited; staff-identified content, language, speed, audibility, charging, and recovery constraints.	Provide site-relevant multilingual content and clear start, use, and recovery cues
Social mediation	All 4 observed indicators were highest with staff facilitation; staff also described prompting and onboarding as necessary.	Consider early facilitation and brief staff onboarding and assess their usefulness directly with visitors and staff
Organizational embedding	Staff requested a named owner, support contact, content process, maintenance, troubleshooting, and protected time.	Assign ownership and integrate support, updates, maintenance, and evaluation into workflow

Discussion

Main Findings

This mixed methods pilot examined how a socially assistive robot was received in a pediatric outpatient setting and which conditions shaped practical acceptance. Across all 4 observed indicators (looking at the robot, approaching it, touching it, and using the robot's screen or app), interaction was lowest when the robot was present without explanation, increased when a poster clarified its role, and was highest when an intern invited and demonstrated use. Staff accounts provided a complementary implementation perspective rather than a direct explanation of visitors' experiences. Staff evaluated the robot as a service tool whose value depended on a concrete role, relevant and multilingual content, technical support, workflow fit, and visible organizational ownership.

Taken together, observed visitor behavior and staff perceptions informed the provisional mediated acceptance framework. The robot's hardware, location, and interface did not change across the 3 field phases; the surrounding support did. The results should nevertheless be read as descriptive associations. The sequential naturalistic design does not establish that the poster or facilitator alone caused the observed differences.

Interpretation in Light of Prior Research

The stepwise increase in recorded behavior can be interpreted in light of technology acceptance theory. Clearer information and human facilitation are possible mechanisms consistent with perceived usefulness, ease of use, social influence, and facilitating conditions [16,17]. These constructs were not measured among visitors, so this interpretation remains theoretical rather than an empirical explanation of their behavior.

The stronger visible responsiveness of children also aligns with pediatric and hospital robotics literature. Earlier reviews suggest that children often engage readily with social robots when interaction is concrete, emotionally legible, and easy to interpret [3,8]. Staff interviewees described movement, voice, games, and distraction during waiting as meaningful for children. Staff evaluated the robot in terms of usefulness, reliability, and support burden, while field notes described adult visitors more often taking supervisory or instrumental roles. These observations and staff accounts do not establish differences in perceptions between children and adult visitors, although they suggest questions relevant to research on the broader care ecosystem [7,9]. The present age-related interpretation remains cautious because it is based on field notes and lacks linked age-by-behavior counts.

The findings also support a sociotechnical interpretation of acceptance. Staff did not ask for a more spectacular or more human-like robot. They asked for clearer functions, stronger content, multilingual capacity, easier troubleshooting, training, and responsibility. These priorities mirror barriers and enablers identified in implementation reviews, where maintenance, workflow fit, reliability, and stewardship influence whether robots move beyond pilot visibility [10,11,19,20]. Staff descriptions of child engagement and usability constraints raise hypotheses relevant to enjoyment, social presence, trust, and ease of use in the Almere model [18]. These constructs were not assessed directly among visitors and should not be treated as observed acceptance outcomes.

The integrated framework adds a practical bridge between these traditions (Table 2). TAMs explain why a person may approach and try the robot, while implementation research explains whether the organization can sustain the service. In this study, observation documented behavior under different support conditions, while staff accounts identified perceived longer-term needs such as content management, troubleshooting, and ownership. The contribution is a provisional synthesis of these complementary perspectives, not evidence of visitors' perceived usefulness, trust, or acceptance.

Practical Implications

The descriptive observation patterns and staff accounts suggest that hospitals could evaluate clear signage, explicit interaction cues, and early human facilitation when introducing SARs. These approaches may support visitor interaction, but their effects on visitors' understanding, uncertainty, and perceived usefulness were not assessed in this study. Staff-identified wayfinding, waiting time engagement, parent guidance, and simple procedural information as potential use cases. These suggestions are consistent with roles discussed in the broader health care robot literature [4,5], but the present observations did not establish successful task completion or benefits perceived by visitors. Such functions should therefore be

XSL•FO
RenderX

evaluated with children, parents or guardians, and other adult visitors before broader implementation.

The interviews also suggest that a child-facing function may create indirect value for other people in the care environment. A robot that holds a child's attention during waiting may make navigation or preparation easier for parents and may reduce some routine interaction demands on staff. Future deployments should assess this potential chain of benefit directly; visible engagement alone is insufficient. Hospitals should therefore define expected outcomes for each use case, such as successful wayfinding, reduced uncertainty, or perceived helpfulness, and select measures that correspond to those outcomes. Staff accounts emphasized the need for organizational anchoring. A hospital should, with the help of relevant stakeholders, define what the robot does, where its task begins and ends, who updates content, who responds to faults, and how value will be assessed. Staff onboarding should include routine use and common recovery situations. The framework in Table 2 summarizes staff-informed priorities for implementation; whether these priorities improve visitor experience or sustained use requires further evaluation.

Limitations and Future Research

This was a single-site pilot, and the quantitative strand used descriptive observation without inferential testing. The 3 conditions were sequential and conducted on different dates, so temporal variation in visitor flow or other unmeasured contextual factors may have contributed to the differences. Counts represented anonymous passages, and repeat passages could not be identified. The 4 behavior indicators could overlap; their summed count per 100 passages does not measure the proportion of visitors who interacted, the depth or duration of engagement, or acceptance. Age category was not linked to individual behavior codes; therefore, age-related observations were limited to descriptive interpretation of the field notes.

The qualitative strand involved a small, staff-focused sample that differed from the observed visitor population. Children, parents or guardians, and other adult visitors were not interviewed. Although staff had direct exposure to the robot, their accounts reflect their own perceptions and cannot establish visitors' perceived usefulness, ease of use, reasons for interacting, or acceptance. Because the datasets were not linked at the person level, integration cannot establish that staff-identified factors explain the observed behavioral differences. Exact staff age, gender, tenure, and job title distributions were not collected to protect the identity of employees. The study also did not directly measure child emotion, anxiety, trust, or satisfaction, although affect is central to social HRI [8,26]. These limitations restrict transferability and indicate that the 4-domain framework remains provisional.

Future research should combine in situ observation with ethically appropriate direct feedback from children, parents, adult visitors, and staff. Repeated or counterbalanced implementation periods and privacy-preserving person-level behavior coding would permit stronger comparison of contextual and age-related patterns. Longer follow-up should examine whether multilingual content, stronger interaction design, staff onboarding, explicit ownership, and maintenance arrangements support sustained use after novelty effects diminish.

Comparative work should also examine different robot-mediated tasks and settings. Wayfinding may require clear movement, stopping, and destination cues, while waiting time engagement may require age-appropriate content, audibility, and careful limits on distraction. Multisite studies could distinguish context-specific findings from more general implementation requirements and test whether the 4-domain framework remains useful across pediatric hospitals with different layouts, languages, staffing models, and patient populations.

Conclusions

In this single-site descriptive pilot, observed visitor interaction with Temi V3 was higher under poster support and staff facilitation than at baseline. Staff perceived potential value in wayfinding, child engagement during waiting, and basic guidance, and they identified content, language coverage, reliability, support, and workflow fit as important implementation considerations.

These complementary findings informed a provisional mediated acceptance framework comprising role clarity, interaction affordance, social mediation, and organizational embedding. The framework is an interpretation of observed behavior and staff perspectives, not a demonstration of visitors' acceptance or of the effects of specific support mechanisms. Direct feedback from children, parents or guardians, and other adult visitors, together with longer-term evaluation, is needed to assess these proposed conditions and their contribution to sustained use.

Acknowledgments

The authors thank the staff of Tallinn Children's Hospital for their collaboration.

Generative AI Use

Generative AI tools (ChatGPT 5.6; OpenAI) were used to assist with language refinement and schematic figure preparation. The authors checked all scientific content, numerical values, references, and interpretations.

Abstract

Background: The rapid growth of social media has transformed communication, with more than 5.66 billion users worldwide in 2025 who spent an average of 141 minutes daily on platforms such as Facebook, Instagram, WhatsApp, YouTube, and TikTok. Nurses frequently use social media to exchange work-related information, communicate with others, and relieve stress. While social media can support professional development, excessive or inappropriate use at work may compromise patient care. Despite widespread use, research on nurses' demographic factors and actual workplace social media behaviors remains limited.

Objective: The aim of the study was to determine how nurses use social media at work and how their demographic characteristics (eg, gender, age, and number of years working in health care) are related to the use of social media at work.

Methods: This study used a quantitative, descriptive, exploratory, and nonexperimental empirical research design. Data were collected via a survey administered to a convenience sample of 132 nurses. The sample comprised of 98 women (74.2%) and 34 men (25.8%). The questionnaire consisted of 17 statements related to social media use in the workplace. A statistical significance level of $P<.05$ was applied. Descriptive statistics and inferential statistical tests were used.

Results: Nurses used Facebook the most and spent between 45 minutes and 1 hour per day on social media. Study participants reported that they primarily used social media for communication with colleagues and acquiring new knowledge. They also used social media for its technical functions, such as file sharing. Nevertheless, a substantial number of nurses reported using social media during working hours, and many had experienced creating an uncomfortable situation after declining social media interactions with patients or colleagues.

Conclusions: This study highlights the important topic of social media use at work by nurses. The study found that nurses frequently used social media, primarily for professional communication and knowledge acquisition. While most demonstrated positive use patterns, the findings indicate that social media use during work may pose potential challenges to professionalism. These results highlight the need for clear guidelines and training to ensure that nurses use social media responsibly, maintaining both professional boundaries and personal integrity. Encouraging mindful and regulated use can enhance the benefits of social media while minimizing risks in the health care setting.

KEYWORDS

nursing; hospitals; digitalization; social media; informatics

Introduction

We are witnessing rapid technological development in the 21st century, particularly in relation to the internet and social media. Social media is defined as a group of online applications that enable the creation and sharing of content generated by users [1]. More than a decade ago, Kaplan and Haenlein [2] defined five main categories of social media: (1) collaborative projects (eg, Wikipedia), (2) blogs or microblogs (eg, X), (3) content communities (eg, YouTube), (4) social networking sites (eg, Instagram and Facebook), and (5) virtual gaming worlds (eg, Second Life).

Unlike traditional media, where users are usually passive recipients of information, social media platforms enable individuals to actively participate in creating and sharing content with others, which is precisely why they are becoming an increasingly important means of communication and connection among people [3]. In recent years, the use of social media has thus become an indispensable part of everyday life for many around the world. Many people spend several hours a day on platforms such as Facebook, Messenger, and Instagram, whether to maintain contacts, exchange information, or for entertainment and relaxation [4]. The data show that the number of social media users worldwide had reached 5.66 billion in October 2025, or approximately 70.8% of the global population [5].

XSL•FO
RenderX

Statistics indicate that in 2025, users spent an average of 141 minutes per day on social media. Compared with data from 2015, this number is on the rise, as daily social media use at that time was just 111 minutes [6]. The data further reveal that the most frequently used social media platforms are Facebook (Meta Platforms), Instagram (Meta Platforms), WhatsApp (Meta Platforms), YouTube (Alphabet Inc), and TikTok (ByteDance) [7].

According to research by Lefebvre et al [8], 87% of the 397 nurse respondents had an active user account on at least one social media platform. It was also found that older age is associated with less frequent use of social media. A study conducted by Wang et al [9] using a sample of 658 nurses revealed that approximately 56% of participants spend between 1 and 3 hours per day using social media. The majority (67.2%) reported that they use social media to exchange work-related information with colleagues. At the same time, 50.3% stated that they had witnessed inappropriate posts by their colleagues. In their study of a sample of 43 nurses at the tertiary health care level, Al-Rumhi et al [10] found that all the participants used social media, most commonly WhatsApp. They also found that most nurses spend 1 to 2 hours a day on social media. The authors state that the main motives for nurses to use social media were to acquire knowledge, communicate, and establish contact with patients, thus reducing the number of hospital visits.

To maintain professional integrity and ensure the responsible use of social media, the American Nurses Association has issued the following recommendations for its use [11]: (1) maintain professionalism online, (2) avoid sharing patient posts, (3) exercise caution when posting photos from the workplace, (4) avoid establishing contact with patients and their families, (5) refrain from disparaging one's employing organization, and (6) avoid posts that cast the nursing profession in a negative light. The growing use of social media in health care has highlighted the importance of digital professionalism, defined as the expression of professional values and behaviors in digital environments. As nurses increasingly engage with social media, understanding how these platforms are used in workplace contexts has become an important aspect of maintaining professional boundaries and ethical practice [12-14].

Through work, people satisfy numerous needs—biological, social, economic, and psychological—including the need for success, belonging, recognition, respect, and self-fulfillment. At the same time, work involves a system of social interactions that shape people, connect them with others, and significantly influence their quality of life [15,16]. Nurses who are exposed to high workloads are much more prone to burnout, absenteeism, and errors in patient care [17]. This is why mobile phones and social media are digital tools that health care workers often use in their work to reduce stress and divert their attention from work-related burdens [8,18]. However, excessive use of social media during working hours can compromise the quality of patient care [19] because it can reduce the time and energy devoted to patient-focused tasks, thereby reducing their work performance [20].

Since nurses are frequent users of social media [10,18], it is crucial that they recognize the associated dangers, especially when it comes to using it at work. Although evidence from numerous countries shows that nurses frequently use social media, there is still limited research examining how demographic factors relate to its use within the nursing profession, and there is a lack of data describing how such behaviors occur and what factors influence them. Moreover, most of the existing research focuses on general attitudes and perceptions, whereas few studies offer empirical quantitative data on actual patterns of social media use by nurses at work. Additionally, research from many regions focuses primarily on nursing students rather than practicing nurses, leaving a knowledge gap about the experiences of nurses already engaged in direct patient care.

The purpose of this research was to describe social media use among nurses. The specific aim of the study was to examine how nurses use social media in the workplace and to explore how their demographic characteristics (eg, gender, age, and years of experience in health care) are associated with social media use at work. We thus set the following research questions: Which social media platforms do nurses use most frequently? How much time do nurses spend on social media each day? For what purposes do nurses use social media at work? How are the demographic characteristics of nurses related to their use of social media at work?

Methods

A descriptive, exploratory, and nonexperimental method of empirical research was used with a survey technique.

Research Instrument Description

The research instrument was developed by Landers and Callan [21]. To ensure conceptual and linguistic accuracy in the Slovenian context, the original English instrument was translated independently by 4 translators. Each translated version was subsequently back-translated into English and compared with the original instrument to identify potential discrepancies and ensure semantic consistency. The translated versions were reviewed and discussed by the research team, and any differences were resolved through consensus.

The questionnaire assessed work-related social media use broadly, including behaviors and interactions connected to the workplace context. It comprised 17 items rated on a 5-point Likert scale ranging from 1 (disagree) to 5 (agree), organized into 2 conceptually distinct subscales. The first subscale assessed the positive, purposeful dimensions of work-related social media use and contained 8 items (eg, "I use social media to learn how to do my job better" and "I use social media to contact colleagues when I cannot reach them in any other way"). The second subscale consisted of 9 items measuring negative or problematic social media behaviors in the workplace (eg, "My coworkers have been offended by something I posted on social media" and "I discuss negative feelings about patients or colleagues on social media").

Before computing the composite work-related social media use score, all 9 items from the negative-behavior subscale were reverse-scored to ensure directional consistency across all 17 items. The composite score was then calculated as the mean of

XSL•FO
RenderX

all items, with higher scores reflecting greater overall work-related social media use. Although the questionnaire originally consisted of 2 conceptually distinct subscales (beneficial work-related use and potentially harmful workplace behaviors), the overall composite score was calculated as the mean of all items to capture a broader continuum of overall work-related social media behavior. This approach is consistent with the conceptual framework proposed by Landers and Callan [21], where work-related social media use may range from professional and beneficial engagement to problematic or inappropriate workplace behaviors. Therefore, higher composite scores reflected a more favorable overall pattern of work-related social media use.

Internal consistency was satisfactory for both subscales, with a Cronbach α of 0.73 for the positive-purpose subscale and 0.74 for the negative-behavior subscale [22].

The third section of the questionnaire collected demographic data, including gender, age, years of nursing work experience, level of health care, and field of employment. Participants were additionally asked whether they held a management position, which social media platforms they used most frequently, and their average daily time spent on social media.

Prior to the main study, the Slovenian version of the questionnaire was pilot-tested among 20 nurses to evaluate clarity, comprehensibility, and cultural appropriateness. Minor linguistic adjustments were made based on participant feedback before the final version was distributed to the study sample. The responses obtained from the pilot testing were not included in the final analysis of this study.

Research Sample Description

The target population of this study consisted of nurses employed in clinical practice across different health care settings in Slovenia. Eligible participants were individuals currently employed in nursing or direct health care practice who were actively involved in patient care or clinical work environments. To be included in the study, participants had to be currently employed within the health care system and willing to voluntarily complete the online questionnaire. Individuals not currently employed in clinical health care practice, health care students, retired health care workers, and respondents who did not complete the questionnaire in full were excluded from the final analysis.

A convenience sample was used in this study, and recruitment was conducted through snowball sampling, with the survey completed and distributed via online communication channels and social media. The snowball sampling approach was chosen because the study aimed to recruit nurses working across different health care settings in Slovenia, while online recruitment allowed efficient access to geographically dispersed participants. The survey link was initially distributed through professional and personal online communication channels, including social media platforms commonly used by health care professionals. Participants who accessed the questionnaire were subsequently encouraged to share the survey link with other nurses within their professional networks, thereby enabling broader recruitment through peer-to-peer distribution. To reduce potential sampling bias, the survey was distributed through multiple communication pathways (eg, social media platforms, email communication, professional networks, and direct person-to-person sharing) rather than relying on a single online platform, allowing access to nurses from different health care institutions and professional backgrounds.

The introductory page of the online questionnaire was viewed by 303 people. A total of 145 respondents began completing the questionnaire, and we included the responses of 132 respondents who completed the entire online questionnaire in our analysis. The research included 98 (74.2%) women and 34 (25.8%) men. The respondents were on average aged 34.3 (SD 10.33) years. The youngest respondent was aged 19 years and the oldest was 60 years. A total of 17 (12.9%) respondents were employed in primary health care, 88 (66.7%) in secondary health care, and 27 (20.5%) in tertiary health care. Most respondents were employed in hospital wards, for example, surgical (n=33, 25%), internal medicine and pediatrics (n=14, 10.6%), and intensive care (n=13, 9.8%). Respondents who did not select one of the offered work areas most often cited emergency medical services, radiology, and oncology as their areas of expertise.

Twenty-eight (21.2%) respondents had completed secondary education, 86 (65.2%) had completed higher education, 17 (12.9%) had completed postgraduate master's education, and 1 (0.8%) respondent had obtained a doctorate. Most nurses (n=92, 69.7%) who participated in our study are employed as registered nurses. Thirty-one (23.5%) respondents stated that they performed a managerial function, while 101 (76.5%) respondents stated that they did not.

The largest group of nurses had been employed in health care for 1 to 4 years (n=26), followed by those employed for 20 years or more (n=25).

Description of the Research Process and Data Processing

The survey was conducted using the open-source online survey application 1KA (version 26.09.01; Faculty of Social Sciences, Ljubljana, Slovenia). The questionnaire was distributed via online media and other communication channels using a snowball sampling method. Respondents had the opportunity to complete the questionnaire from July 9, 2025, to November 9, 2025.

Only fully completed questionnaires were included in the data analysis. The data were analyzed using SPSS (version 26.0; IBM Corp). Basic descriptive statistics were calculated (frequency, range, mean, and SD), and statistical tests were performed: the Kolmogorov-Smirnov test and 1-way ANOVA, independent-samples *t* test, 1-sample *t* test and the Tukey post hoc test. The level of statistical significance was set at $P<.05$. During the analysis, we created a composite variable, "Use of social media at work," which combined all 17 statements about the use of social media at work into a single variable.

Ethical Considerations

This study was conducted under Umbrella Ethical Approval for Research granted by the University of Primorska (approval

XSL•FO
RenderX

4264-19-6/23). Before completing the questionnaire, respondents gave their consent to participate in the survey. All procedures in this research were conducted in accordance with ethical guidelines outlined by the Declaration of Helsinki [23] and followed institutional protocols to ensure quality, integrity, and ethical responsibility.

Results

Overview

In our study, we found that Facebook was the most frequently used social media platform (n=113), followed by Instagram (n=105), Viber (Rakuten Viber; n=61), TikTok (n=55), and WhatsApp (n=34). Respondents who did not select one of the options provided most frequently cited LinkedIn (Microsoft), Pinterest (Pinterest, Inc), and BeReal (Voodoo).

Most respondents (45/132, 34.1%) spend between 45 minutes and 1 hour per day on social media, followed by those who use social media from 1 to 2 hours a day (37/132, 28%), 30 to 45 minutes a day (23/132, 17.4%), more than 2 hours a day (20/132, 15.2%), and less than 30 minutes (7/132, 5.3%).

The highest average value in the first set of questions (4.11, SD 1.09) was obtained for the statement that nurses use social media to contact colleagues when they cannot reach them in any other way. This indicates that one of the most important aspects of social media use is communication with colleagues. Nurses also rated relatively highly (mean 2.98, SD 1.24) the statement that they use social media to learn how to do their job better, which means that one of the purposes of using social media is education. In this section, they also expressed a high level of agreement (mean 2.95, SD 1.31) with the statement that they use the technical functions of social media, such as file sharing, to perform their work tasks, which reveals an additional aspect of their social media use. The lowest average value in this section of the questionnaire was for the statement that the respondents establish contact with potential new patients via social media (mean 1.40, SD 0.84). The average beta coefficient for the variability of the first set of statements was β=0.48. The full sociodemographic characteristics of the respondents are shown in Table 1.

The statements in the second set of questions mostly describe negative situations related to the use of social media at work, which means that lower average values for the statements indicate a lower level of agreement with the statements offered, suggesting less problematic use of social media. Nurses rated the statements in this section of the questionnaire low on average. Nevertheless, 2 statements received higher ratings, namely that nurses used social media when they should have been working (mean 3.08, SD 1.27) and that they had caused an unpleasant situation in the past by refusing to connect with colleagues, superiors, or patients via social networks (mean 2.75, SD 1.41). The lowest rating (mean 1.22, SD 0.59) was given to the statement that patients had posted information about respondents on social media that damaged their reputation at work, which means that most respondents had not yet encountered this situation. In this part of the questionnaire, the average beta coefficient measuring the variability of the statements was β=0.43.

Table . Sociodemographic characteristics of the participants (N=132).

Characteristics	Participants, n (%)
Gender	
Man	34 (25.8)
Woman	98 (74.2)
Health care setting	
Primary level (eg, primary health center and nursing home)	17 (12.9)
Secondary level (eg, general hospital)	88 (66.7)
Tertiary level (eg, clinical center)	27 (20.5)
Area of work	
Surgical ward	33 (25)
Internal medicine ward	14 (10.6)
Pediatric ward	14 (10.6)
Gynecological ward	9 (6.8)
Specialist outpatient clinic	8 (6.1)
Primary care clinic	3 (2.3)
Nursing home	3 (2.3)
Home care nursing	5 (3.8)
Intensive care unit	13 (9.8)
Emergency room	7 (5.3)
Other (eg, radiology ward)	23 (17.4)
Education level	
High-school diploma	28 (21.2)
Bachelor’s degree	86 (65.2)
Master’s degree	17 (12.9)
Doctoral degree	1 (0.8)
Professional role	
Practical nurse	2 (1.5)
Professional nurse	19 (14.4)
Registered nurse	92 (69.7)
Other (eg, managers)	19 (14.4)
Years of experience in nursing	
<1	20 (15.2)
1-4	26 (19.7)
5-9	23 (17.4)
10-14	19 (14.4)
15-19	19 (14.4)
≥20	25 (18.9)

The 2 statements that had the biggest impact (β=0.61) on the variability of the entire questionnaire were that respondents use the technical functions of social media to perform work tasks and that they ask for help via social media when they encounter problems at work (Table 2). The *P* values for all 17 statements were obtained with a 1-sample 2-tailed *t* test.

XSL•FO
RenderX

Table . Values of statements related to the use of social media at work.

Statement	Score, mean (SD; range)	β[a]	*P* value
I use social media to contact my coworkers when I am unable to reach them by other means.	4.11 (1.09; 1-5)	0.49	<.001
If I find something on social media that could harm the reputation of my coworkers or our organization, I let people know.	3.61 (1.21; 1-5)	0.21	.01
I have used social media when I should have been working.	3.08 (1.27; 1-5)	0.54	<.001
I have used social media to learn how to perform better in my job.	2.98 (1.24; 1-5)	0.47	<.001
I have taken advantage of the technical features of social media (such as file sharing or scheduling functions) to accomplish work tasks.	2.95 (1.31; 1-5)	0.61	<.001
I have created an uncomfortable situation by refusing connections with coworkers, supervisors, or patients via social media.	2.75 (1.41; 1-5)	0.55	<.001
I access social media while I am doing other work.	2.38 (1.14; 1-5)	0.53	<.001
I request help from people on social media when I am having trouble solving a problem at work.	2.33 (1.19; 1-5)	0.61	<.001
I use my organization's official social media presence to network.	2.32 (1.43; 1-5)	0.42	<.001
I communicate with patients via social media.	1.62 (1.04; 1-5)	0.50	<.001
Other people at work have been offended by something I posted on social media.	1.61 (1.07; 1-5)	0.40	<.001
Through social media, I have entered a personal relationship with a patient or a colleague that I should not have had.	1.53 (0.93; 1-4)	0.43	<.001
I have stolen information or other content from social media and used it as if it were my own work.	1.42 (0.81; 1-4)	0.31	<.001
I connect with potential new patients through social media.	1.40 (0.84; 1-4)	0.50	<.001
I have discussed negative feelings toward patients or coworkers on social media.	1.37 (0.77; 1-4)	0.34	<.001
I have done poor quality work using my organization's social media accounts.	1.25 (0.57; 1-4)	0.46	<.001
Patients posted information about me on social media that harmed my reputation at work.	1.22 (0.59; 1-4)	0.28	<.001

[a]β: beta coefficient

Inferential Statistics

Due to the normal distribution of the data, which we determined using the Kolmogorov-Smirnov test (Kolmogorov-Smirnov statistic=0.07; *P*=.20), we used parametric tests for further analysis.

Using the independent-samples *t* test, we did not find any statistically significant differences in the use of social media

XSL•FO
RenderX

between genders (t_{130}=0.177; P=.86; Cohen d=0.04). Additionally, we did not find statistically significant differences in the use of social media according to the managerial function of nurses (t_{130}=–0.294; P=.77; Cohen d=–0.06).

A 1-way ANOVA showed statistically significant differences ($F_{2,129}$=7.399; P=.001; η^2=0.103) in the use of social media at work among nurses at the primary (mean 40.47, SD 7.61), secondary (mean 38.75, SD 8.44), and tertiary (mean 32.18, SD 8.08) levels of health care. The Tukey post hoc test showed statistically significant differences (P=.001) between nurses at the secondary and tertiary levels of health care. Nurses employed at the tertiary level achieved lower (more favorable) values, which indicated a more professional and thoughtful use of social media compared with nurses at the secondary level of health care.

By contrast, ANOVA did not detect statistically significant differences in the use of social media based on professional role ($F_{4,127}$=1.268; P=.29; η^2=0.03) and years of nursing experience ($F_{5,126}$=0.883; P=.49; η^2=0.03).

Discussion

Principal Findings

The purpose of our research was to describe the use of social media at work among nurses. We found that the most frequently used platform among the respondents was Facebook, with 113 nurses using it. Other frequently used social media platforms were Instagram, Viber, TikTok, and WhatsApp. Gamor et al [24] reported similar results, finding that health care workers most frequently used Facebook, WhatsApp, Twitter (now X), YouTube, and Instagram. In line with our results, Van Ravenswaay et al [25] found that Facebook was the most frequently used social media platform among health care professionals.

In our study, we found that nurses are frequent users of social media, using it for an average of 45 minutes to 1 hour per day. Surani et al [26] came to a similar conclusion, finding that most nurses spent between 31 and 60 minutes per day on social media. Ahmead et al [27] found that 33.5% of nurses spent more than 1 hour per day on social media, while 45% of them used social media for 1 to 3 hours per day. They also found that 76.6% of nurses spent more than 1 hour per day on social media at work. In our study, we found that nurses often used social media when they should have been working. The use of social media in the workplace can be potentially harmful to nurses' work. Wilson [28] identified 5 key risks associated with the use of social media at work, namely (1) a decline in employee productivity, (2) information leaks, (3) damage to the institution's reputation, (4) cybercrime, and (5) data loss due to insecure passwords. Geraghty et al [29] concluded that the use of social media at work can be detrimental to nurses, as it reduces their level of attention and perception of the situation at hand, which are both crucial for the safe care of patients.

We found that nurses primarily used social media to communicate with colleagues when they could not reach them by other means. This was also reflected in the more frequent use of social media platforms whose primary purpose is communication (eg, Viber and WhatsApp). Gamor et al [24] also found that one of the primary purposes of social media use for nurses was to communicate with colleagues. In addition, we found that nurses often used social media to learn how to do their jobs better. The results were consistent with the findings of other studies, which concluded that nurses often used social media for professional development, knowledge exchange, and education [24,30,31].

In the second part of the questionnaire, the respondents agreed least with the statement that they use social media to establish contact with patients. It is very important for nurses to be professional in their work, to have clear boundaries, and to maintain a professional relationship with their patients to protect their integrity. At the beginning of the rise of social media, Aylott [32] noted that the line between personal and professional relationships between nurses and patients was quickly blurred, especially with the help of social media, which facilitates communication and accessibility. Valente [33] notes that nurses may receive friend requests from patients on social media, but that crossing professional boundaries in this way can significantly damage their professionalism. At the same time, such behavior undermines patients' trust in the work of nurses and damages the therapeutic relationship.

Because nurses often do not respond to friend or follow requests on social media or other calls to establish contact with patients or colleagues, they can quickly create an uncomfortable situation. Most of the participants in our study agreed that they had been in such a situation before. Unhjem [34] found that nurses often received friend requests from patients on Facebook, and that most nurses decided to accept them, even though this negatively affected their professionalism and integrity and represented a serious violation of the therapeutic relationship with the patient. The author concluded that most nurses accepted the friend requests because otherwise they felt uncomfortable and guilty about rejecting patients. Importantly, this discomfort is not merely interpersonal but is grounded in ethical and patient safety concerns. Professional standards emphasize that nurses must respect defined boundaries when interacting with patients, whether in clinical settings or on social media [35]. From an ethical and patient safety standpoint, several key risks are associated with social media interactions involving patients, such as the blurring of professional boundaries [34] and compromising confidentiality and privacy [36]. It is thus crucial for all nurses to maintain their professionalism outside the clinical settings where they work and not to enter into personal relationships with patients, thus preserving their professionalism.

In our study, we found that nurses employed at the tertiary level of health care used social media in the most professional manner. This could be attributed to clearer policies and guidelines in tertiary health care institutions, which encourage the professional use of social media in clinical practice [37]. This suggests that environments with more established governance provide a clearer framework for social media use that mitigates any potential risks (such as confidentiality concerns and unprofessional behavior). However, this study did not find any statistically significant differences in social media use based on age (P=.99), gender (P=.11), or job position (P=.29). In contrast,

XSL•FO
RenderX

Nelson-Brantley et al [31] found that the use of social media differed statistically significantly among nurses based on demographic data such as age, job position, and type of employment. Lefebvre et al [8] found that age affected the frequency of social media use and that the use declined with increasing age. This could be attributed to the fact that younger nurses generally have easier and more frequent access to mobile phones.

This study contributes to the growing body of literature on digital professionalism and social media use in health care by providing empirical evidence on how nurses use social media within clinical work environments. While previous research has often focused on nursing students or general attitudes toward social media, our study offers insight into actual workplace behaviors among practicing nurses. The findings have relevance beyond the Slovenian health care setting, as health care institutions worldwide increasingly face challenges related to digital professionalism, maintaining professional boundaries, and ensuring the responsible use of social media in clinical practice. Our results thus contribute to the broader international discussion on how digital technologies are reshaping professional behavior within modern health care systems.

Study Limitations and Suggestions for Future Research

While nurses in clinical practice participated in the study, the study relied on nonprobability sampling methods and included a small, uneven sample and spanned different health care settings, which limited the ability to generalize the findings to the broader global nursing workforce. Future research should therefore include a larger sample of nurses across more diverse regions of the world and systems to enable meaningful comparisons across different countries and contexts. Through multicountry comparative studies, researchers could examine how cultural norms affect nurses' social media use in the workplace.

Another limitation of this study relates to the use of snowball sampling and online recruitment through social media and digital communication channels. Because participation depended on voluntary engagement with online distribution channels, the study may have disproportionately reached nurses who are more familiar with or more active users of social media. This may have introduced self-selection bias and potentially overrepresented participants with higher levels of digital engagement. Consequently, the findings cannot be generalized to the broader nursing population.

Another limitation is the low number of respondents holding master's or doctoral degrees, which prevents the findings from being extended to highly educated nurses. In the future, it is imperative that more educated nurses participate in the study.

Another limitation of the study is that no a priori sample size calculation or power analysis was performed before data collection. Consequently, the adequacy of the sample size for detecting smaller effects cannot be fully determined and should be considered when interpreting the findings.

Furthermore, the cross-sectional design of the study limits the ability to draw causal conclusions regarding the relationships between demographic characteristics and social media use. The findings represent a snapshot of participants' behaviors and perceptions at a single point in time. Moreover, data were collected using a self-report questionnaire, which may have introduced response bias and social desirability bias. Participants may have underreported potentially inappropriate social media behaviors or overreported professionally desirable practices, which could have influenced the accuracy of the reported findings.

Additional qualitative research is recommended using in-depth individual interviews or multiple focus groups to gain a more comprehensive understanding of how nurses use social media in clinical practice, and experimental research is also recommended. In this way, researchers could test how specific types of social media influence nurses' decision-making and how they affect their work performance.

Conclusions

Our study demonstrates that nurses in clinical practice are frequent users of social media, primarily for professional communication with colleagues and for acquiring new knowledge. However, our findings also highlight potential challenges, including the use of social media during work hours, which may distract nurses from patient care. It is essential that nurses maintain professional boundaries and adhere to ethical guidelines when using social media in the workplace, both to safeguard patient safety and to uphold the integrity of the nursing profession. By promoting responsible and purposeful social media use, health care institutions can support nurses in leveraging digital tools to enhance professional development, collaboration, and the overall quality of patient care.

Funding

The internal research program SiZDRAV – Synergy between Health, Work and Education is cofunded by the University of Primorska within the framework of the Internal Call for Internal Program Groups at the University of Primorska and by the Public Agency for Scientific Research and Innovation of the Republic of Slovenia (ARIS) through stable funding under the heading Development Pillar of Funding.

Abstract

Background: Monitoring of vital signs is a critical component of nursing care, facilitating the early detection of complications, enabling the observation of the progression of health status, and providing a foundation for diagnosis and therapeutic decision-making. It is instrumental in ensuring quality of care. Contactless measurement methods, such as radar-based sensors, have the potential to enable continuous monitoring of respiration, heart rate, and bed activity without disturbing or stressing vulnerable patients.

Objective: The study investigates the feasibility, usability, acceptance, and implementation of a contactless digital vital-signs monitoring system. The objective is to ascertain the suitability of the device for incorporation into the workflow of nursing personnel and to assess implementation factors in an inpatient setting. Additionally, the study examines user acceptance and satisfaction among nursing staff.

Methods: A total of 13 nursing staff members from geriatric and dialysis departments participated in this mixed methods pilot study. Following the installation of the technology, the participants underwent a 30-minute training period to become acquainted with its operation. Thereafter, the system was subjected to a 4-week trial period. Quantitative data were collected at 3 points in time using the Technology Usage Inventory and the System Usability Scale. Furthermore, measurement protocols were evaluated to compare the time required for the standard and contactless measurement methods. Qualitative data were collected subsequent to the conclusion of the trial through the implementation of focus group interviews. Ethical approval and informed consent were obtained.

Results: The study results suggest that the average intention to use among the study participants (n=13) reached a relatively high level after 4 weeks (mean 85.5, SD 107.7). However, variation was observed when the 2 nursing wards were considered separately (geriatrics: 28.4 vs dialysis 199.8). The monitoring system was evaluated based on the System Usability Scale, which yielded a mean score of 74.5 (SD 10.5), indicating good usability. The nurses reported a perceived enhancement in their sense of security and monitoring oversight during routine care. Additionally, potential time savings were observed due to a reduction in disruptions to established processes. However, compared with conventional real-time monitoring, disadvantages were identified and technical requirements were defined.

Conclusions: The use of contactless measurement in the assessment of vital signs holds considerable promise for enhancing the efficacy of nursing care, particularly in contexts where manual measurements have been the prevailing standard. In order to further explore technical capabilities in a nursing context, additional research needs to be conducted.

Introduction

Contactless Monitoring Systems in Hospital Care

The continuous monitoring of vital signs constitutes a fundamental element of professional nursing care and clinical decision-making. The regular assessment of parameters such as heart rate, respiratory rate, and physical activity enables early identification of clinical deterioration, supports timely interventions, and contributes to patient safety [1]. Beyond its clinical relevance, systematic monitoring and documentation of vital signs also play a crucial role in quality assurance processes and provide legal protection for nursing staff by ensuring transparency and traceability of care interventions.

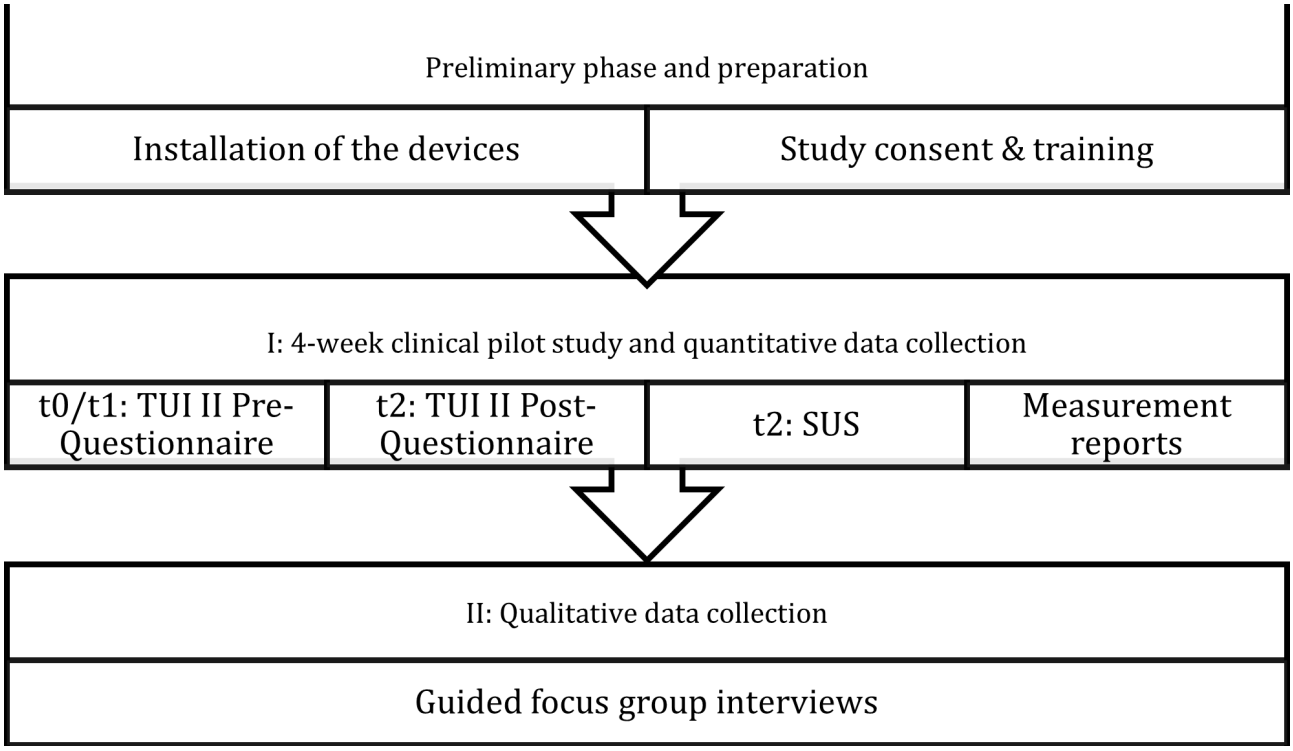
In many inpatient settings, vital signs are still manually measured at predetermined intervals [2,3]. Conventional monitoring methods often require direct physical contact with patients, which can impose a significant burden or elicit feelings of stress. Furthermore, this contact has been identified as a risk factor for the development of delirium [4], particularly among vulnerable populations, including older patients, individuals with cognitive impairment [5], patients who had a stroke [6], and those with fragile skin conditions [7]. Repeated manual measurements can disrupt patients' rest and sleep. This disruption may, in turn, have a deleterious effect on the recovery and overall well-being of the individual.

Advancements in digital health technologies have precipitated the development of contactless monitoring systems, including radar-based sensors capable of detecting micromovements of the chest wall [8]. These systems provide continuous monitoring of respiration, heart rate, and bed activity without the use of electrodes, cuffs, or wearable devices. In addition to enhancing patient comfort, contactless monitoring technologies have the potential to reduce nursing workload, support early detection of critical events, and enhance safety within care processes. However, the extent of evidence regarding the usability, acceptance, and integration of these tools into nursing workflows remains limited [9].

Aim

The present study explores the feasibility and usability of implementing a contactless digital monitoring system (Neteera 130H-Plus) [10] within a hospital environment. The aim of this study is to determine the extent to which the device integrates into the workflow of nursing personnel, to assess the device's acceptance among users, and to identify potential barriers to implementation. From the perspective of the users, the following assessments will be formulated: time savings, work simplification, satisfaction, and usability in everyday clinical practice.

Methods



Study Design

This study was designed as a feasibility study to assess the usability and feasibility using a mixed methods approach [11,12]. The study used a sequential explanatory design, combining quantitative and qualitative data collected in 2 consecutive phases. The qualitative phase followed the quantitative phase to further explain and contextualize the results. This approach was selected to comprehensively evaluate the feasibility, usability, and acceptance of the Neteera 130H-Plus system in routine clinical nursing care. Methodological reporting was carried out using the GRAMMS (Good Reporting of a Mixed Methods Study) checklist [13] (Checklist 1).

The study was conducted under real-world conditions without altering standard clinical workflows. Patients were monitored using both the Neteera system and standard-of-care monitoring devices, enabling direct comparison without influencing clinical decision-making. Following a preparatory phase that included device installation, consent procedures, and staff training, a 4-week clinical pilot phase was conducted with quantitative data collection. The Technology Usage Inventory II (TUI II) [14] was used to assess acceptance at baseline (T0/T1) and postintervention (T2). System usability was measured using the System Usability Scale (SUS) [15] at T2. Concurrently, measurement reports and time records were generated. Subsequently, qualitative data were gathered through guided focus group interviews to contextualize and expand upon the quantitative findings (Figure 1).

XSL•FO
RenderX

Figure 1. Study design and procedure. SUS: System Usability Scale; TUI: Technology Usage Inventory.

In this study, *usability* refers to the ease of use of the system, *feasibility* to its practical implementation under routine clinical conditions, *usefulness* to the perceived benefit to nursing work, *acceptance* to the overall evaluation of the technology, and *intention to use* to the willingness to continue using the system in clinical practice.

Setting and Participants

The study was conducted at a German university hospital in 2 inpatient clinical departments: an acute dialysis department and a geriatric ward. The wards were selected to reflect different clinical settings, each with distinct monitoring requirements and workflows. The study population comprised registered nurses and nursing professionals involved in the routine monitoring of vital signs in inpatient, predominantly bedbound patients. The inclusion criteria comprised active involvement in vital sign monitoring and direct use of the Neteera system during clinical shifts. Participation in the study was voluntary and conducted during regular working hours. The study sample included all nursing staff available at the time of recruitment in the 2 wards. The sample size was selected pragmatically, in line with the exploratory nature of a feasibility study and without a formal power calculation. Patients were not actively recruited for study participation; however, they were provided with study-specific information about the technology being tested. Monitoring was performed exclusively in the context of routine clinical care. All patients continued to receive standard monitoring, independent of the study, ensuring that no clinical decisions were based on data generated by the investigational system.

Intervention

The Neteera 130H-Plus is a contactless, radar-based remote patient monitoring system designed to continuously capture health parameters (heart rate, heart rate variability, respiration rate, depth, and amplitude) and activity tracking (micromovements, time in bed, and bed exits) without direct patient contact. The device is mounted above the patient's bed (on the wall or headboard) and operates through clothing and bedding (Figure 2). All data are transmitted in encrypted form to a cloud-based platform hosted on European Union–based servers. The nursing staff underwent a structured, 30-minute training and onboarding session prior to system implementation. A live demonstration of the available functions was provided at the nursing station, followed by immediate system testing. The research staff were on site at all times to answer any questions.

XSL•FO
RenderX

Figure 2. Central positioning of the "Neteera" sensor (Neteera product photo).

Quantitative Data Collection and Analysis

Acceptance, Usefulness, and Usability

The TUI II [14] was used to assess technology acceptance and perceived usefulness at 3 distinct time points: baseline (T0, following the training), mid-study (T1, after 2 weeks of use), and end of study (T2, after 4 weeks of use). The TUI methodically assesses numerous dimensions. The TUI II is a parallel version of the TUI and is used to minimize learning effects or measurement repeatability errors when participants complete the questionnaire multiple times (eg, for preinteraction and postinteraction comparisons with a technology). At T0, the "TUI-II Pre" was administered. The questionnaire comprises 8 items, which relate to both the new technology and the general attitude toward technologies, and it allows statements to be made on the "curiosity" and "technology anxiety" scales. At T1 and T2, the "TUI-II Post" was used to assess 6 scales: "interest," "accessibility," "usefulness," "ease of using a technology," "skepticism," and "intention to use (ITU)," comprising a total of 18 items [14]. The ITU scale is a 10-centimeter-long visual analog scale used to assess agreement with given statements. The end points of the scale (eg, "agree" vs "disagree") serve as anchors for assessing the degree of agreement. The distance between the scale end point representing complete disagreement and the participant's mark is measured in millimeters for each of the 3 items. The 3 values are then summed to obtain an ITU score ranging from 0 to 300. The ITU scale assessed the ITU, intention to purchase, and desire for access to the technology. Lower scores indicate higher ITU, willingness to purchase, and readiness for access. Usability was additionally assessed using the SUS [15]. The SUS was administered after 4 weeks of system use (T2) and consisted of 10 items rated on a Likert scale.

Time Required for Vital Sign Measurement

The potential time savings were assessed by documenting the time required (in seconds) to monitor pulse and respiratory rate, both with and without the Neteera device. The documentation was carried out by a nurse in the geriatric ward, who followed a standard protocol. The following components were documented: preparation, measurement, documentation, and deviations or delays during measurement.

The quantitative data were analyzed descriptively using IBM SPSS Statistics version 2. The results were reported as mean scores and SDs according to the respective scoring manuals.

Qualitative Data Collection and Analysis

Following the testing phase and completion of the quantitative surveys, focus group interviews were conducted with nursing staff from both wards to identify experiences, perceived benefits, barriers, and implementation requirements. The focus groups were conducted using a semistructured interview guide. The guide was developed in accordance with established standards of qualitative research and tailored to the research objectives (see Multimedia Appendix 1). The interview guide explored participants' initial impressions and practical experiences with the Neteera system, with a particular focus on usability and its integration into daily nursing workflows. The investigation further examined the perceived benefits and limitations regarding patient safety, quality of care, and the influence of specific clinical settings on system use. Finally, participants were asked to reflect on future roles, necessary improvements, and overall expectations for the implementation of contactless monitoring technologies in nursing practice.

All discussions were audio-recorded, transcribed verbatim, and pseudonymized prior to analysis. Qualitative content analysis was conducted in accordance with the structured approach

XSL•FO
RenderX

proposed by Kuckartz and Rädiker [16] using the MAXQDA 2022 software (VERBI Software GmbH), integrating deductive and inductive category development. This method is particularly well-suited for the systematic analysis of extensive qualitative data. It integrates deductive category formation based on the research questions with inductive further development from the material. The transcripts were initially coded according to the interview guidelines and research objectives by one researcher and subsequently by a second researcher. Subsequently, the discrepancies in the coding were reviewed and discussed. Additional subcategories were inductively added based on the material. The transcripts were coded thematically to identify recurring patterns, perceived benefits, and challenges related to system use and integration into nursing care processes.

The qualitative findings were used to explain and contextualize the quantitative results, particularly differences in usability, acceptance, and perceived usefulness across the 2 clinical settings.

Ethical Considerations

The study was conducted in accordance with the Declaration of Helsinki and Good Clinical Practice guidelines. Ethical approval was obtained from the responsible institutional ethics committee prior to study initiation. All participating nursing professionals provided written informed consent. Data were pseudonymized and stored in encrypted form in accordance with the General Data Protection Regulation. The study received ethics approval from the ethics committee of the Medical Faculty of Martin Luther University Halle-Wittenberg (approval number 2025 - 047, April 30, 2025) and was registered at the German Clinical Trials Register (DRKS00036910). Written informed consent was obtained from all participants, and no financial compensation was provided.

Results

Pilot Study Outcomes

A total of 16 devices were installed in the 2 wards, distributed across 7 patient rooms (n=3 geriatrics, n=4 dialysis). The study staff administered 3 training sessions on site, each lasting approximately 30 minutes. A total of 21 nurses were trained in the system and its use (n=14 geriatrics, n=7 dialysis). The 4-week clinical trial phase began immediately afterward.

Quantitative Results

In the context of geriatric care, a total of 9 (64.3%) nurses completed the questionnaire survey. In the dialysis care setting, 4 (57.1%) nurses completed the survey.

Technology Acceptance

High scores on the TUI II scale indicate a high degree of expression within the designated dimension. Conversely, low scores indicate a low degree of expression [14]. Table 1 presents the mean values obtained from the scales at the 3 distinct measurement time points. For scales with 3 items, the total scale value ranges between 3 and 21 (b), and for scales with 4 items, between 4 and 28 (a). The highest values were recorded on the scales “interest” (T1=22.1; T2=20.9) and “usefulness” (T1=22.6; T2=23.6), with the former decreasing as expected and perceived usefulness being highest at the end of the trial. Skepticism decreased over the 4-week observation period (T1=8.3; T2=7.1), although it was already very low at the baseline. Due to missing responses, not all scales could be calculated in full. Consequently, the total sample size varies and is reported separately for each measurement point in column N.

Table . Technology Usage Inventory II subscale scores across measurement time points (T0-T2).

Scale	Range	T0		T1		T2	
		n	Mean (SD)	n	Mean (SD)	n	Mean (SD)
Curiosity	4 - 28	15	17.6 (5.1)	—[a]	—	—	—
Fear of using technology	4 - 28	16	8.0 (3.2)	—	—	—	—
Interest	4 - 28	—	—	14	22.1 (3.9)	15	20.9 (3.7)
User-friendliness	3 - 21	—	—	11	18.9 (1.8)	13	18.2 (2.3)
Usefulness	4 - 28	—	—	14	22.6 (5.5)	14	23.6 (3.2)
Skepticism	4 - 28	—	—	10	8.3 (3.6)	10	7.1 (3.0)
Accessibility	3 - 21	—	—	5	12.0 (3.4)	6	11.8 (3.6)

[a]Not applicable.

The ITU subscale was also examined using a group-specific evaluation (geriatric ward and dialysis) of the 3 subscales. This finding explains the substantial disparities observed, the origin of which warrants further investigation through a subsequent qualitative survey of nursing personnel. The maximum total score that can be attained is 300, with higher scores indicating a lower willingness to use. As demonstrated in Table 2, a clear discrepancy in scores is observed between the 2 wards. The geriatric ward demonstrated low total scores of 40.8 (T1) and 28.4 (T2) on the ITU scale, indicating a high willingness to use. In contrast, the dialysis respondents showed a heightened degree of caution, as evidenced by a diminished propensity to use the device with scores of 195.5 (T1) and 199.8 (T2).

XSL•FO
RenderX

Table . Intention-to-use (TUI[a] II) scores in geriatric and dialysis wards at T1 and T2[b].

TUI II item	T1, mean (SD)		T2, mean (SD)	
	Geriatrics	Dialysis	Geriatrics	Dialysis
Would you want to use this technology?	12.6 (16.0)	66.3 (37.3)	12.6 (16.0)	12.6 (16.0)
Would you purchase this technology?	19.7 (28.4)	66.8 (37.8)	16.2 (24.9)	65.0 (35.3)
Would you want to have access to this technology?	8.6 (10.1)	62.5 (34.4)	5.1 (8.1)	66.2 (37.4)
Total intention to use	40.8 (51.2)	195.5 (109.0)	28.4 (41.8)	199.8 (111.3)

[a]TUI: Technology Usage Inventory.

[b]Lower values indicate a higher intention to use.

System Usability

The mean overall SUS score was 74.5 (SD 10.5), with values ranging from 58 to 98. According to the SUS manual, a system is considered usable if it attains a score of 68, which was achieved in this study. A comparison of ward-specific scores showed that the SUS score was 76.2 (SD 12.1) for the geriatric ward and 71.0 (SD 5.7) for the dialysis ward. This indicates slightly lower perceived usability in the dialysis ward compared with the geriatric ward. The nursing staff (n=15) evaluated a series of statements using a scale ranging from 1 (“strongly disagree”) to 5 (“strongly agree”). These are presented in Multimedia Appendix 2. The system is described as straightforward to operate (ie, ease of use), with minimal training requirements. The values align with the ITU results on the TUI II scale.

Time Saving

A total of 31 measurement situations were meticulously observed and documented in the geriatric ward using a standard measurement protocol. The vital parameters of heart rate and respiratory rate were determined through the measurement of time in seconds. As shown in Table 3, radar-based measurement was considerably faster, with an average completion time of 20.3 (SD 16.2) seconds compared with 133.8 (SD 69.8) seconds for the conventional method. In 7 (22.6%) cases, delays or challenges in using the Neteera system were described. In 5 instances, the values were not displayed in real time at the desired moment. In 2 cases, it was necessary to reenter the user credentials due to a system logout that occurred in the interim.

Table . Comparison of the standard measurement method and the Neteera system (in seconds) (N=31).

Measurement method	Mean (SD, range) (s)
Manual measurement	133.8 (69.8, 50-380)
Radar-based measurement	20.3 (16.2, 6-60)

Qualitative Results

Findings from the Focus Groups

Following the completion of the trial period, 2 focus groups were conducted, comprising 4 participants in the geriatric ward and 3 in the dialysis unit. The interviews lasted between 26 and 32 minutes. Initially, primary categories were delineated in accordance with the research interests. In an iterative process, these categories were refined during the analysis and supplemented with subcategories. The coding of the 8 primary categories was conducted in close proximity to the data and was grounded in the perspectives of the nurses interviewed. The coded text passages were subsequently summarized by category and condensed for content.

Handling and Usability

The category of handling and usability includes statements on the user-friendliness of the dashboard, training, and practical limitations in everyday use. The operation of the system was characterized as uncomplicated and intuitive. Even those with limited technological expertise reported that the system was straightforward to use. The training was deemed adequate:

> *Well, I have to say, I'm from a generation that didn't grow up with computers and I don't know a whole lot about them, but I got along just fine. I think it’s easy to use. I think we can all manage it.*

However, it was noted that external factors, including bed position, sensor placement, or interference (eg, bed gallows, elevated positioning), can substantially impact transmission stability. Repeated display failures resulted in additional work and frustration, as the nursing staff were compelled to examine the cause of the missing measurements directly at the patient’s bedside. These findings are consistent with the quantitative usability results, as reflected in the overall SUS score of 74.5, indicating good usability and ease of use.

Integration Into Nursing Workflows

Integration of the system into existing workflows emerged as a pivotal category. The ability to collect data without directly disturbing patients, especially during nocturnal hours, was highlighted as a positive feature. Caregivers reported that

XSL•FO
RenderX

nighttime routine activities, such as medication preparation, were interrupted less frequently and that there was a greater sense of security because vital signs could be monitored continuously:

> *It simply means that we can collect data at night without having to wake patients.*

The system was perceived as beneficial due to its capacity to offer an overview of patients' conditions, thereby obviating the necessity for repeated in-person visits. From the participants' perspective, these measures contributed to enhanced work organization and a subjective sense of safety.

This perceived advancement in workflow integration is consistent with the high ratings achieved in the TUI II dimensions of "usefulness" and "user-friendliness" (Table 1).

Positive Usage Situations

This category comprises specific clinical application scenarios in which the Neteera system has been demonstrated to be particularly beneficial. The aforementioned participants primarily included medical and nursing issues in which progress data contributed to clinical decision-making.

One example cited was its use in patients with respiratory diseases, where changes in breathing could be monitored over time:

> *Well, I once had a patient with COPD who we had newly prescribed a new spray for, and she was always experiencing acute shortness of breath. The doctor came and asked how her breathing was, so we looked at the progression and saw what the curve looked like, and that helped us at that moment. Because we could see in black and white how things had progressed. I think that's great for things like that.*

The system was also described as helpful in situations requiring continuous monitoring in general wards, as it enabled selective, close observation without requiring continuous physical presence.

The findings from these cases align with the high perceived usefulness reported in the quantitative data (TUI II), particularly in the geriatric ward, where there was a high level of ITU.

Negative Usage Situations

Within this category, critical feedback is summarized. A large number of complaints concerned the lack of real-time measurements and unclear update intervals for vital signs. This was perceived as a significant limitation in nursing areas that performed circulation-intensive treatment procedures:

> *But we couldn't see on the tablet how often the heart rate was updated. So we couldn't tell, because it wasn't a real-time measurement, it was a fixed number that stayed the same. Our [dialysis] ECG monitoring [electrocardiogram] really shows the current heart rate, and that changes constantly.*

In addition, participants reported frequent measurement failures and significant deviations from established standard procedures (eg, electrocardiogram monitoring). The observed discrepancies have led to a decline in confidence in the accuracy of the measured values. As a result, interest in using the system decreased.

> *Everyone stood there comparing their patients, but then something didn't work and interest waned. Yes. You could tell.*

These limitations are reflected in the lower ITU values at the dialysis unit (Table 2). This finding is consistent with the independent benefit because lower ITU values can be interpreted as a prerequisite for subsequent use. The qualitative results provide a valuable explanation for the quantitative differences observed between the units, particularly the lower acceptance levels in contexts requiring real-time monitoring and high measurement reliability.

Opportunities and Benefits for the Nursing Process and Outcomes

A wide range of potential benefits of the system for the nursing process was identified. Wireless monitoring and the reduction of physical constraints were perceived as key benefits for patients. These features were expected to enhance safety and reduce agitation, particularly in patients at risk of delirium, restlessness, or falls.

> *Actually, all of the patients we have here [geriatric ward] are at risk of delirium. Patients who have delirium definitely benefit from it. Patients who have a disturbed day-night rhythm definitely benefit from it. Hypoactive delirious patients.*

The ability to perpetually assess the respiratory rate, a parameter that has not been systematically documented in conventional nursing practice, has furnished nurses' novel perspectives into the early identification of stress, anxiety, or pain:

> *Without this technology, we would not do this, of course. We would not measure respiratory rate at night. If it can be collected in this way, we can then draw conclusions and take action. Perhaps the patient is in pain, perhaps they are anxious, and so on and so forth.*

Earlier detection of nocturnal events may be possible without interrupting patients' sleep. These perceived benefits are consistent with the high ratings for "usefulness" and "interest" found in the quantitative results. The findings are complemented by the qualitative data, which illustrate how continuous monitoring can improve patient safety and support clinical decision-making under specific conditions.

Nursing Workload and Stress

The system received a mixture of favorable and unfavorable reviews with regard to its workload. In situations involving high levels of stress, the implementation of automated vital sign monitoring has been shown to result in a substantial reduction in workload, primarily by eliminating the need for time-consuming manual measurements. The use of this technology has been demonstrated to reduce the necessity for direct observation, thereby minimizing disruptions and enhancing the perception of security:

XSL•FO
RenderX

> *I would have had to check in every five minutes. We were still there, regularly, but still, you felt… you felt more at ease.*
>
> *But for patients at risk of falling who now need some kind of bedside attendance, this could of course lead to a certain reduction in staff numbers in the short term.*

At the same time, participants emphasized that these benefits depend on the system functioning reliably and consistently. These observations are consistent with the time savings identified in the quantitative data, which point to reduced measurement times. The qualitative results indicate that the benefits are contingent on the system's reliability and on further advancements in its functionality, such as blood pressure measurement.

Future Potential and Economic Aspects

The participants formulated explicit expectations for the subsequent evolution of the system. The integration of additional vital signs, especially blood pressure, was identified as an important requirement. The implementation of comprehensive digital documentation, accompanied by a direct link to the hospital information system, would also constitute a considerable development. Furthermore, reliable real-time data transmission and bedside alerting were identified as key requirements for future system development:

> *It's also ideal for some areas of nephrology. It's particularly ideal for adjusting blood pressure medication. It would be great to be able to see what happens or would happen an hour after administering medication.*
>
> *Well, I think that in order to implement this permanently, you would need improved programme stability so that there are fewer disruptive factors, and a HIS interface.*

The system was perceived as potentially cost-effective, especially compared with conventional wired monitoring systems:

> *That's very affordable, because I recently replaced some cables on a monitor and that cost €400 for just one monitor. That would be quite interesting for us.*

These expectations for further system development are consistent with the high overall interest and willingness to engage with the technology reported in the TUI II results (Tables 1 and 2). The qualitative data suggest that future adoption depends on meeting the identified technical and structural requirements.

Challenges and Barriers to Implementation

Finally, technical, organizational, and structural barriers were discussed. While nurses were generally open to digital systems and did not perceive a risk of dehumanized care, they expected some patients to be skeptical of the technology.

> *This is also extremely important for nursing staff. It has nothing to do with dehumanization or anything like that. It's simply about having the security of having data available at night as well.*

A perceived need for additional patient information was identified:

> *Many [patients] were initially worried that it was a camera, that they were being filmed. That was always their first thought, but then they were actually quite open. No one said, "No, for God's sake, I don't want that".*

The primary barriers to implementation identified included a high susceptibility to malfunction, an absence of real-time capability, inadequate interfaces, and an insufficient trial period. It was also emphasized that the system's full potential could only be realized if all rooms were fully equipped and seamlessly integrated into existing IT structures.

The identified barriers provide a contextual framework for understanding the variability in quantitative acceptance scores, particularly the lower ITU in more technically demanding settings (Table 2). Technical reliability and system integration emerged as critical factors for successful implementation.

Discussion

Principal Findings

The objective of this study was to assess the feasibility and applicability of implementing a contactless, radar-based monitoring system in an inpatient setting from the perspective of nursing professionals.

The findings indicate that the Neteera 130H-Plus system is perceived as usable and potentially beneficial for nursing care, particularly in settings where vital signs are traditionally measured manually and intermittently. While quantitative results support the system's usability, qualitative data provide additional insights into the integration of nursing workflows, perceived safety gains, and setting-specific limitations. The findings indicated notable discrepancies in acceptance and ITU between the geriatric and dialysis wards. The results underscore the pivotal role of contextual factors in the implementation of digital monitoring technologies within nursing practice.

Technology Acceptance and ITU

The quantitative results indicate a high level of acceptance of and willingness to use radar-based, contactless monitoring among nursing staff, particularly in the geriatric ward.

The SUS score indicates that the system is usable and exceeds the commonly accepted threshold [15], suggesting that the system can be handled effectively by nursing staff with limited training. Participants described the system as easy to use, suggesting a high level of usability. This finding is consistent with previous studies on digital assistive technologies in inpatient care. The extant literature demonstrates that usability is a prerequisite for sustained adoption in clinical practice [17], but it is not sufficient on its own.

The TUI II subscales "interest" and "usefulness" showed consistently high scores throughout the observation period. However, perceived interest demonstrated a slight decline, while perceived usefulness reached its peak at the conclusion of the 4-week test phase. This finding suggests that the nursing staff

XSL•FO
RenderX

regarded the implementation of the system as both practical and conducive to the effectiveness of nursing processes. Concurrently, the degree of skepticism remained minimal, underscoring a fundamental openness to the technology. A thorough analysis of the TUI II subscales reveals variations between the wards. In the geriatric ward, the values were found to be particularly low, which correspond to a high level of willingness to use the system. In contrast, the dialysis ward exhibited elevated values, indicating a more cautious approach among nursing staff. The observed discrepancy can be attributed to context-specific implementation factors. The qualitative findings indicate that acceptance was shaped not only by system usability but also by the degree to which the technology aligned with existing monitoring practices, workflow requirements, and expectations regarding real-time information. Workflow and monitoring requirements were in place due to the standard practice of continuous monitoring and real-time feedback in the dialysis ward (eg, via electrocardiogram and blood pressure measurement). Consequently, nursing staff required immediate access to relevant data that are continuously updated, particularly in situations involving medical decisions and emergency situations. The lack of reliable real-time data and concerns about measurement accuracy diminished the perceived relevance of the data for nursing decision-making. A recent systematic review described deviations in radar-based measurement methods. The review emphasizes that measurement accuracy is highly dependent on the measurement environment and conditions. Interfering factors, such as movement or device positioning, may influence measurement accuracy. The present findings are consistent with the observations made in the study [8].

Moreover, the system enables continuous vital sign monitoring without disturbing patients, a novel feature particularly relevant during nocturnal hours in the geriatric ward. The participants reported that continuous monitoring without disturbing patients contributed to a perceived sense of security among nursing staff. This finding is consistent with previous literature, which demonstrates that contactless monitoring is particularly well-received in settings involving vulnerable patients, as it enhances comfort and safety [18].

Time Savings and Impact on Workload

During the pilot phase, a key benefit identified was the reduction in time required to measure selected vital signs using radar-based monitoring. However, the potential for greater time savings remains limited in the absence of radar-based blood pressure measurements. The findings should be interpreted with caution, as the calculations were based on data from a single nurse and were not performed under controlled conditions. Further comparative measurements under controlled conditions are needed to draw reliable conclusions. The qualitative findings indicate that a reduction in interruptions, a decline in visits to the bedside, and the implementation of continuous background monitoring contributed to a subjective feeling of relief and enhanced safety, particularly during night shifts. However, nursing staff also emphasized that the efficacy of these benefits is contingent upon the stability of the system. The occurrence of technical issues, including delayed data display and forced logins, reduced the initially observed time savings. These issues also increased workload and frustration among nurses. Consequently, the efficacy of time savings appears to be contingent on the reliability of system performance [19] and the availability of blood pressure measurements.

Strengths and Limitations

This design enabled the contextualization and interpretation of quantitative usability and acceptance data through qualitative insights. The qualitative findings helped explain why most participants perceived the system as easy to learn and use despite occasional technical difficulties. The integration of 2 distinct clinical wards allowed the exploration of different nursing workflows and monitoring requirements, which is particularly relevant for feasibility research [19]. Conducting the study under real-world conditions without modifying standard care processes strengthened ecological validity and provided realistic insights into everyday nursing practice. It is imperative to acknowledge the active involvement of academically trained nursing staff, particularly those specializing in geriatrics, in the clinical setting. Consequently, while the time expenditure measurements were conducted on a limited scale and are not generalizable, they were executed under real-world conditions. In light of a single observer, one ward, and the limited number of observations, the findings related to time-measurement should be interpreted as exploratory observations rather than estimates of implementation-related efficiency gains.

Several methodological limitations should also be considered. The sample size was limited and based on pragmatic considerations, which is common in feasibility studies but restricts generalizability. Furthermore, the 4-week intervention period may not have been sufficient to establish stable routines or to assess long-term acceptance, particularly in technically demanding clinical environments.

Implications for Nursing Practice

The observed discrepancies among nursing wards underscore the notion that the efficacy of implementation is contingent upon the prevailing context. In settings characterized by acute demands for real-time data, such as dialysis nursing care, the necessity for robust and frequently updated systems is paramount to ensure trust and use. In less intensively monitored areas, such as geriatrics, the implementation of a system that provides vital parameters continuously, albeit not necessarily in real time, has been demonstrated to effectively alleviate workflow burdens, support monitoring processes, and reduce workflow interruptions from the perspective of nursing staff [20]. From the perspective of the nurses surveyed, blood pressure measurements play a decisive role in the complete mapping of basic parameters. Therefore, the potential time savings in vital sign measurement can only be partially evaluated, as blood pressure and pulse are usually measured in separate cycles. While intuitive design and ease of use are frequently associated with positive user perceptions, broader contextual factors such as workflow integration, organizational support, training, and alignment with clinical needs fundamentally influence whether technologies are sustainably adopted in nursing care environments [17,21].

Despite the system's capability for activity tracking, this feature had little influence on nurses' evaluations. The use of activity

XSL•FO
RenderX

data for clinical decision-making was limited, as these data were often perceived as less relevant than vital parameters such as respiratory rate and heart rate. In some acute care settings, nursing staff have reported that automated activity tracking is of secondary importance compared with direct clinical observation, which may reduce the added value of such systems in these contexts. The quantitative and qualitative findings suggest that activity tracking may be more relevant in long-term care or settings with lower staff-to-patient ratios, where continuous direct observation is less feasible. In these contexts, changes in movement patterns may serve as early indicators of functional decline, delirium, or fall risk [22]. The limited use of this feature in the present study does not necessarily reflect a lack of potential value but highlights the importance of adapting technological functionalities to the specific needs and constraints of the care environment.

Implications for Future Research

In order to validate these findings and investigate acceptance and usability across a broader range of clinical contexts, larger, multicenter studies are necessary. A comparative analysis of contactless monitoring systems and established monitoring technologies could provide further insights into the added value of radar-based approaches. The potential time savings observed in this study should be further evaluated using systematic cost-benefit analyses. In addition, subsequent research should concentrate on outcome-oriented end points, including the impact of continuous contactless monitoring on the early detection of clinical deterioration, the incidence of delirium, fall rates, and care-sensitive outcomes. The integration of activity tracking warrants further investigation. Finally, greater emphasis must be placed on the implementation of research findings in clinical care. A comprehensive understanding of how training concepts, technical support, interoperability with hospital information systems, and participatory implementation strategies influence long-term acceptance is imperative for translating technological feasibility into sustainable clinical practice [21,23].

Conclusions

The outcomes of this study indicate that, from the perspective of nursing personnel, contactless monitoring may be both feasible and acceptable in selected inpatient settings. A comparison of geriatric and dialysis care reveals the necessity of implementing strategies tailored to local workflows and requirements. The findings from this study, which employed a mixed methods approach, suggest that the clinical context and specific application conditions influence how new technology is perceived and used. These findings underscore the importance of aligning implementation approaches with technical performance, clinical workflows, and nursing needs. In light of the exploratory nature of the study and the methodological limitations imposed on it, further research is necessary. This additional research should be conducted in larger and more diverse clinical settings. Future studies should validate these findings and investigate long-term usability, acceptance, and integration into routine care.

Acknowledgments

The authors would like to thank the nursing professionals who supported this study and tested the monitoring system in routine clinical practice. Their engagement and practical expertise were essential for the successful implementation of the study. Furthermore, the authors acknowledge the technical staff for their support in integrating the system into the clinical infrastructure. They are grateful to the nursing directorate, the nursing leadership of the participating departments, and the staff council for their support and for enabling the implementation of this study. The authors gratefully acknowledge Ms Mary Land for her careful English editing and for improving the clarity and quality of the manuscript. AI-based language tools (DeepL Write/DeepL Academic, DeepL SE, Cologne, Germany; accessed March 2025; ChatGPT, OpenAI, GPT-4; accessed March 2025) were used for the section-by-section review of the manuscript to support language quality, clarity, and readability. All suggestions were critically evaluated, revised where necessary, and approved by the authors.

Funding

The financial support for this study was obtained from the Open Access Publication Fund of the Martin-Luther-University Halle-Wittenberg. All study-related activities were financed using institutional resources of the corresponding academic chair. The manufacturer, Neteera Technologies Ltd, provided the monitoring devices free of charge for the purpose of application testing. The manufacturing company of Neteera had no role in the study design, data collection, analysis, or interpretation; manuscript preparation; or the decision to submit the manuscript for publication.

Abstract

Background: In the past decade, the use of health technologies, such as telemonitoring, video consultations, and patient portals, has increased. However, it remains unclear how these technologies have influenced nurse-patient communication. Additionally, little is known about the role nurses play in recognizing and supporting limited (digital) health literacy patients.

Objective: This study aimed to explore which health technologies are currently being used in a hospital context and how nurse-patient communication has changed as a result. Furthermore, we sought to identify the practices nurses use and the barriers they experience in recognizing and supporting patients with limited digital health literacy.

Methods: This is a qualitative descriptive study that used semistructured interviews with nurses working in a hospital (n=21). The interview guide was partly based on the 6-function model of medical communication by de Haes and Bensing. All interview transcripts were analyzed by 2 independent coders using a combination of deductive and inductive approaches.

Results: According to the nurses, health technologies have impacted all 6 functions of nurse-patient communication. They noted improvements in gathering information, providing information, enabling disease and treatment management, and responding to patients' emotions. In contrast, technology made fostering the relationship more difficult, and technologies were seldom used in shared decision-making. Nurses identified limited digital health literacy through intuition, observation of verbal and nonverbal cues, and direct questioning. To support patients with limited digital health literacy, nurses relied on building trust, involving the social network, tailoring communication, and offering additional support. High workload and limited knowledge were the main barriers to applying these practices.

Conclusions: Our findings show that health technologies have significantly influenced nurse-patient communication in the hospital setting. The results highlight the need for tailored training programs to strengthen nurses' competencies in identifying and supporting patients with limited digital health literacy. This is essential to ensure more comprehensible and accessible care and promote equitable patient engagement with health technologies.

Introduction

One of the essential elements of nursing care is communication with patients and their relatives [1]. Communication between nurses and patients serves different functions. The 6-function model of de Haes and Bensing [2] distinguishes the following functions from the viewpoint of the care professional: (1) fostering the relationship, (2) gathering information, (3) providing information, (4) decision-making, (5) enabling disease and treatment-related behavior, and (6) responding to the

XSL•FO
RenderX

emotions of patients. In practice, these functions overlap and interact during nurse-patient communication. Nevertheless, they are important for positive patient outcomes, including patient satisfaction, adequate diagnosis and treatment, treatment adherence, and even health [3,4].

Over the past decade, the rapid rise of the internet and digital health technologies has begun to reshape the context in which these communication functions take place. Nowadays, patients have access to health information via the internet and social media and to specific information about their own health status and treatment via the hospitals' patient portal. Apps exist for self-management, and the telemonitoring of vital functions may provide care professionals with continuous insight into bodily functions, which was formerly not possible. In addition, nursing consultations are increasingly being conducted digitally, via email, chat, or video conferencing, and health education is frequently supported by websites and videos.

These developments offer various benefits, such as improved patient insight into their health and reduced care costs and patient burden due to fewer hospital visits [5]. However, the benefits may not exist for all patients, and patients with limited health literacy may not experience the benefits from these health technologies. Patients with limited health literacy find it difficult to find, comprehend, or apply health information; they are not able to take responsibility for their health and find communication difficult [6]. The aforementioned digitalization of care requires even more skills of patients, such as the ability to operate devices and navigate on the web, understand and use health apps, and apply digitalized nursing consultations. These skills are called digital health literacy or eHealth literacy [7]. Digital health literacy is not only a technical skill set but the ability to engage with digital technologies in effective, safe, and helpful ways to achieve health goals [8]. It is influenced by sociodemographic factors, such as age, educational level, income, perception of the internet as a health source, and social support [9-11]. In the Dutch context, these inequalities are substantial: it is estimated that 1 in 3 people have a limited health literacy [12], and approximately 20% experience difficulties with digital skills [13]. It can be expected that, in a hospital setting, this number may even be higher because patients may experience tension. For example, in acute or critical care settings, patients may be sedated or intubated, limiting direct interaction, and nurses often need to communicate primarily with family members rather than the patients themselves.

Given these challenges, nurses could play an important role in the care of patients with limited (digital) health literacy, starting with their ability to recognize these patients. However, recognizing these patients is difficult, and studies have shown that nurses often overestimate the health literacy of their patients [14,15]. In addition, limited evidence exists regarding nurses' knowledge and awareness of patients' (digital) health literacy, and little is known about the practices nurses currently use to identify patients with limited (digital) health literacy in clinical practice. Once patients with limited (digital) health literacy have been identified, nurses need practices to support them. Although previous qualitative research has examined how nurses assess and support patients with limited health literacy, attention to the digital component is mostly lacking. In addition, concept descriptions of (digital) health literacy are available in the literature, and evaluations of nursing practices or interventions remain scarce. Given the increased use of health technologies, an understanding of recognizing and subsequently supporting patients with limited (digital) health literacy by nurses in hospitals is needed.

In conclusion, the increased availability of health technologies is likely to have changed nurse-patient communication. Yet, to date, only a few studies have examined how the rapid digitalization of health care specifically reshapes the 6 communication functions between nurses and patients in hospital settings. In addition, little is known about how nurses can recognize or support patients who experience difficulties in using these health technologies. Therefore, in this qualitative study, we aim (1) to explore which health technologies are used by nurses within a hospital context and how the 6 functions of nurse-patient communication have changed through the use of these technologies and (2) to examine nurses' current practices, as well as the barriers they experience, in recognizing and supporting patients with limited (digital) health literacy.

Methods

Design and Setting

A qualitative descriptive study was conducted, using thematic analysis of semistructured interviews. The interviews were conducted in Isala, a teaching hospital in Zwolle, and at Windesheim University of Applied Sciences in Zwolle, and a vocational education program at Drenthe College in Meppel, all in the Netherlands. This study is reported in concordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines [16].

Participants

Purposive sampling was used to obtain a heterogeneous sample of nurses, intentionally selecting participants with diverse specialisms and experiences. Inclusion criteria were current employment at Isala, a teaching hospital in Zwolle, the Netherlands, either as a registered nurse or a nurse in training; a minimum of 1 year of clinical experience or completion of at least 1 hospital-based internship; and currently using at least 1 health technology.

Procedures

Potential participants (17 registered nurses and 6 nurses in training) were invited via email, either directly by the researchers or through their supervisor about the study's aim, interview topics, and the implications of participation. Of those invited, 2 did not respond or were unable to participate due to time constraints, while the remaining individuals agreed to participate.

Interviews were conducted a few weeks after the invitations were sent, either face-to-face or via video call. Before each interview, participants provided written informed consent.

Interviews took place between November 2022 and January 2023 at the hospital and were conducted by 2 researchers (EMD and JW), both trained in qualitative research. One researcher

XSL•FO
RenderX

was employed as a nurse researcher at the hospital, and the other was a lecturer at the University of Applied Sciences. A pilot interview was conducted to assess the clarity and structure of the interview guide, leading to minor adjustments in question sequencing.

A total of 21 interviews were conducted, with 17 held in person and 4 online. All interviews were audio-recorded with participants' permission and transcribed verbatim. During most interviews, a student assistant was present to help manage time and ensure all questions from the interview guide were addressed. Interviews lasted between 25 and 54 minutes.

Interview Guide

The interviews were conducted using an interview guide, including 3 main topics.

The Use of Health Technologies and Their Impact on the 6 Functions of Patient-Nurse Communication

The data were gathered using the 6-function model of communication (Table 1) [2].

Table . The 6-function model of communication [2].

Six functions	Explanation
Fostering the relationship	Emphasizes the importance of mutual trust, understanding, and commitment, as well as agreement about each other's roles and expectations
Gathering information	Aims to ascertain a correct interpretation of symptoms and establish an adequate nursing diagnosis
Providing information	Aims to provide understandable, accurate, sufficient, and timely information in a manner appropriate to the patient
Decision-making	Aims to make sure decisions are being based on the information and preferences of patients
Enabling disease and treatment-related behavior	Aims to support patients in treatment adherence and a healthy lifestyle
Responding to emotions	Requires nurses to elicit patients' emotional distress, communicate an understanding of the patient's emotions, and respond with empathy and support

First, nurses were asked how each function was part of the nurses' work and if any health technologies were used in performing this function. Health technology was defined as the application of organized knowledge and skills in the form of devices, medicines, vaccines, procedures, and systems developed to solve a health problem and improve quality of life [17]. An infographic with examples of health technologies (such as video calling, patient portals, and digital leaflets) used in nursing care was presented to stimulate discussions about their own experiences with these health technologies and experiences with other technologies they may have used. Furthermore, nurses were asked if and how these technologies have changed the specific function. Each participant was interviewed about at least 2 functions. If there was enough time, nurses were asked about more than 2 functions. These 2 functions were rotated between interviews so that all functions were addressed equally.

Current Practices in Recognizing and Supporting Patients With Limited (Digital) Health Literacy

The critical incident technique [18] was used to gain insight into current practices in recognizing and supporting patients with limited (digital) health literacy. Nurses were asked to describe a situation where the communication with a patient with limited (digital) health literacy failed, followed by several follow-up questions aimed at elaborating on the situation (eg, "What happened?," "What went wrong?," and "What did you do to fix it?"). Then, the opposite was asked to describe a situation wherein the communication was very effective. Again, nurses were encouraged with follow-up questions to elaborate on the situation. Furthermore, some additional questions were asked to gain insight into their current practices regarding recognition, such as, "Can you assess whether a patient you are seeing for the first time can work with that technology?," and support, such as, "How do you ensure that a patient with limited digital health literacy can work with this technology?"

Barriers to Recognizing and Supporting Patients With Limited (Digital) Health Literacy

Nurses were asked which barriers they experienced in recognizing and supporting patients with limited (digital) health literacy. For example, the following questions were asked: Which barriers do you experience in recognizing patients with limited digital health literacy? And how is this for supporting patients with limited digital health literacy?

Data Analysis

The data were analyzed using a thematic analysis [19] using Atlas.ti 22. Two researchers (EMD, JW) first independently read all transcripts to familiarize themselves with the data and identified relevant text fragments. Coding was conducted independently, and coders met after 3, 6, and 12 interviews to discuss their findings and refine the coding scheme. Any discrepancies were resolved through discussion, and a third researcher (CHCD) was consulted when necessary to reach consensus. After each round of discussion, the coding scheme was further refined. No formal intercoder reliability metrics were calculated, as this is not standard for thematic analysis, in

XSL•FO
RenderX

which the focus is more on finding patterns of meaning rather than on numerical agreement. We combined deductive and inductive approaches: deductive coding was guided by the main research questions, while inductive coding allowed subcategories to emerge from the data. Text fragments were first sorted (deductively) into categories in line with the research questions: changes in the 6 functions of communication, practices to recognize limited (digital) health literacy, practices to support patients with limited (digital) health literacy, and experienced barriers in recognizing and supporting patients with limited (digital) health literacy. Within each category, subcategories were developed inductively, allowing themes to emerge from the data.

Data saturation was assessed following Hennink et al [20], who distinguish between code saturation, the point at which no new codes are identified, and meaning saturation, the point at which a richly textured understanding of the themes is achieved. In our study, no new codes or themes emerged after 16 interviews, indicating that code saturation had been reached. A total of 21 interviews were conducted, ensuring that all research questions were comprehensively addressed and meaning saturation was also achieved.

Ethical Considerations

The study was conducted following the ethical principles of the Declaration of Helsinki. The Medical Research Ethics Committees confirmed that the study (reference number 20221009) is not subject to the Medical Research Involving Human Subjects Act (WMO). Participants provided written informed consent prior to the interview. Participants were able to decline to answer any questions and withdraw from the study at any time up to the time of data analysis. All participant-related data were deidentified and kept by the researcher. Only research team members had access to the data. No compensation was provided, apart from reimbursement for the time participants spent participating in the interview.

Results

Characteristics of Participants

The characteristics of the participants (n=21) are presented in Table 2. One nurse worked at the virtual monitoring center, where patients at home are monitored remotely. A chief nursing information officer and 2 nurse information officers also participated; these roles aim to support the integration of health technologies into nursing practice. Additional specialized roles included an electronic medical record (EMR) key user, who acts as a mediator between EMR developers and clinical staff, and a digital health technology coach (“digicoach”) who supports nurses in using digital tools. No compensation was provided, apart from reimbursement for the time participants spent participating in the interview.

Health Technologies in Patient-Nurse Communication

Nurses indicated using various health technologies, both in the hospital and in the home environment. For example, at the hospital, nurses are using the EMR to report about the patient's condition, use videos to support their education for patients, and use a projector with images (eg, nature, animals, or cities) to calm patients. The mentioned health technologies were divided into 5 categories: e-interaction, e-monitoring, e-education, e-recording, and e-support (Table 3).

Table . Overview of health technologies used by the hospital nurses.

Category of health technologies	Health technology
E-interaction	Video consultation, e-coach, translator, email contact (including sending photos), phone call, and notifications for nurses via the app
E-monitoring	Distant monitoring of measurement directly transferred to EMR[a], online questionnaire about self-reported symptoms, monitoring exercise behavior, and camera surveillance
E-education	Images, digital leaflets, videos, webinars, and websites
E-recording	Electronic medical record, patient portal, and digital diary for family
E-support	Projector with calming images, virtual reality, music, online church services, and VR[b] cycling: stationary bike combined with a screen

Health Technology Influence on Patient-Nurse Communication

Overview

We analyzed nurses' responses regarding whether and how health technologies have affected the 6 functions of communication. According to the nurses, health technologies influenced all 6 functions of nurse-patient communication. They reported positive effects on gathering information, providing information, supporting disease and treatment management, and responding to patients' emotions. In contrast, technology was perceived as making the development of the nurse-patient relationship more challenging, and it was rarely used to support shared decision-making. The results are summarized in Table 4, with + indicating positive changes, – negative changes, and ± changes that were neither clearly positive nor negative, reflecting neutral effect.

Table . How health technologies have positive, negative, or neutral changed the 6 functions of communication.

Functions	Changes
Fostering the relationship	• Increases patients' sense of safety (eg, through camera surveillance) (+[a]) • Lack of eye contact or nonverbal communication (±[b]) • Creates more distance between patient and caregiver (eg, video consultations) (–[c]) • Requires more time to build a relationship (–) • Patients feel less listened to (–) • Less privacy for a patient (eg, through camera surveillance) (–)
Gathering information	• Data are more structured in EMR[d] (+) • Allows measurements to be recorded in the EMR with the patient present (+) • Increases safety through automatic transfer of vital signs into the EMR (+) • Quick and complete data collection via online questionnaires before or during admission (+) • Continuous data collection at home (+) • Reduces number of hospital visits through video consultations (+) • More insight into the home environment (+) • Email consultations offer the opportunity to respond whenever suitable (+) • Enables quick and adequate treatment in the home situation through, eg, sending photos of ostomy (+) • Missing "the clinical view" (±)
Providing information	• Increases patient insight into medical data through, for example, portal (+) • Provides relatives insight into patient well-being via "digital diary" (+) • Increases options for multimodal education, which enhance patient understanding (eg, videos) (+) • Can be sent in advance to enhance patient preparation (eg, digital leaflets) (+) • Check patient understanding in e-education (±) • Check patient understanding in e-education (±) • Some images are too complex and reduce clarity (–)
Decision-making	• Access to (personal) data can contribute to informed decision-making (+) • Retrieving information from EMR is simplified (+) • Online decision aid can contribute to shared decision-making (+)
Enabling disease and treatment-related behavior	• Exercise options to stimulate the patient to healthy behavior (+) • Requires patients to take a more active role through remote monitoring (±)
Responding to emotions	• Can contribute to distraction, for example, through VR[e] (which can reduce pain) (+) • Enables emotional expression via iPad emoticons (+) • Builds reassurance through better understanding of condition via e-education (+) • Enables nurses to inform their colleagues about patients' emotions fostering coordinated care (+) • Enhanced comfort in home situation (+) • Emotional support after admission through, for example, messages (+) • Requires attentive listening to the emotions expressed, as visual cues are not available (±) • Technology can create disruptions, for example, nurse paging systems (–)

Fostering the Relationship

Building trust and fostering the relationship between nurse and patient constitutes the basis for successful nurse-patient communication. According to participants, this function has changed considerably with the increased use of health technologies, such as video consultation and notifications via patient portals and apps, and mostly in a negative way. It causes a lack of eye contact and nonverbal communication, creates more distance between patients and nurses, and requires more time to build a relationship. Some nurses mentioned that their patients feel less listened to because the nurse is typing during the conversation to add results into the EMR. Regarding e-monitoring, nurses thought that this would increase the patient's sense of safety. However, a negative consequence was also noted, namely that (camera) surveillance could compromise privacy. Finally, the nurses indicated that a good relationship could be established if it starts with a face-to-face interaction before the technology is being used, as is illustrated in the following quote:

> *It also does bring a bit of distance but I think you can reduce that distance if you have created trust during a [face-to-face] consultation at the outpatient clinic. And, if you have taken time for that.* [R10]

Gathering Information

The second function of nurse-patient interaction is gathering information: nurses need to gather information about symptoms and health status to reach an adequate diagnosis and treatment (care) plan. According to the nurses, this function has mostly positively changed with the availability of health technology. For example, e-recording provides more structured data of patients and allows a quick search for information, and the possibility to report the provided information into the EMR in the presence of the patient reduces the chances of mistakes. Automatic measurement and transfer of vital signals into the EMR increases safety and reduces workload for nurses. The use of online questionnaires allows for quick and complete gathering of data before or during hospital admission and continuous data collection also at home. The positive changes of e-interaction (eg, video consultations) included more insight into the home environment of the patient and that patients have to come less often to the hospital. In addition, nurses indicated that online consultations are less often interrupted, and email consultations or messages offer the opportunity to respond whenever suitable. For patients with ostomy or wounds, especially, the opportunity to send photos enables quick and adequate treatment in the home situation.

As a downside, nurses emphasized that by e-interaction, they sometimes miss "the clinical view." This makes listening skills particularly important, as is outlined in this quote:

> *It is very different to have a clinical view over the phone or email than live, where you can also watch someone. Yes, you have to listen very carefully and you have to start asking a lot more questions, so you don't just look at how someone is sitting, but you also ask, what did you just do when someone is out of breath? Because I didn't see all that. Where are you right now? Are you standing? So I have to start asking very specific questions about a measurement.* [R8]

Providing Information

The third function of nurse-patient interaction is information provision: nurses have to provide clear information tailored to the patient, for example, information about symptoms, diagnosis, disease, and treatment. Nurses felt that this function was mostly changed in a positive way. Regarding e-recording, the patient portal provides more insight for patients into their personal medical data, and a "digital diary on the ward" provides patients and their relatives insight into nurses' interpretation of patients' well-being and daily activities. Regarding e-education, websites, visualizations, and videos provide options for multimodal education and thereby enhance patients' understanding, as is illustrated in the following quotation:

> *A video with illustrations is a much better tool and easier than a leaflet, I think. Many leaflets that I hand out, turn out to be still unread at the bedside table by the end of the admission.* [R5]

Moreover, education via the internet can easily be sent in advance, enhancing patient preparation and improving personalized communication. On the other hand, one nurse indicated that some images are so difficult that they make the information less understandable. When oral education is replaced by e-education, for example, digital leaflets, it is important to check if the information is found and understood by the patient.

Decision-Making

Nurses play a pivotal role in facilitating shared decision-making by providing information and taking into account preferences. Currently, nurses use a limited number of health technologies in the decision-making process. Regarding e-recording, patient access to (personal) data can contribute to informed decision-making, and retrieving information by nurses from EMR is simplified. E-support, such as online decision aids, can contribute to shared decision-making. Although most interviewed nurses had not yet incorporated online patient decision aids into their daily practice, these technologies were recognized as potentially valuable additions for shared decision-making with patients. This potential valuable was described by one of the nurses as follows:

> *They exist [Patient decision aids], but are not used very often in practice. I was introduced to a digital colorectal cancer decision aid, explaining types of cancer and the advantages and disadvantages of different treatments, help patients choose what they want. I liked that, but in practice, it is hardly used.* [R11]

Enabling Disease and Treatment-Related Behavior

The fifth function includes enabling disease and treatment-related behavior, which involves supporting patients in treatment adherence and promoting a healthy lifestyle. Nurses described different changes in this function resulting from the increased use of health technologies. About e-support, the

XSL•FO
RenderX

implementation of virtual cycling increases exercise options to stimulate the patient to healthy behavior.

Regarding e-interaction, the use of health technologies, such as apps and sending photos by email, facilitates a more active role of patients as they are required to make choices and take actions on their own. For example, patients have to make medication intake changes or have to make changes in the wound care treatment, such as stopping flushing the wound. This more active role is mostly regarded as positive but also requires extra effort and skills of the patient, as becomes clear from the following quote:

> *I always say [to patients]; care at a distance is good care, but it is care in which you are in charge, you have to take the steps yourself. But the patient also needs to understand those steps.* [R10]

Responding to Emotions

Patients often experience a range of emotions, such as anxiety, anger, and sadness, as a result of their disease. Nurses can play a crucial role in identifying and responding to these emotions, which can provide patients with a sense of support, but is also a basis for other functions, such as adequate information exchange, decision-making, and self-management. Nurses mentioned that health technologies mainly caused positive changes in this function. Technologies mentioned under e-support included music, virtual reality, video calling with relatives, and online church services that can provide distraction and support to patients. For example, one nurse explained how projected images could distract and calm patients:

> *For example, you find yourself in a forest that was really an experience, and you notice that patients are really happy with that, so in that way, yes, offering something with images and sound, brings distraction. Being in another world for a moment.* [R2; an image projector was used]

In a similar way, virtual reality can lower the experienced pain, for example, during wound treatment.

In addition, if patients are not able to talk, an app was used that allows them to digitally indicate emotions by selecting an emoticon on an iPad. This technology makes it possible to express emotions without using voice. E-education can establish reassurance because a better understanding of their condition or treatment can reduce emotional stress. Using e-interaction can contribute to enhanced comfort in the home situation and create the opportunity for emotional support after an admission. Additionally, as a result of new opportunities to communicate digitally with patients (such as via messages, phone consultations, and emails), nurses are required to attentively listen to the emotions expressed by patients as visual cues are not available. Finally, e-recording, such as the EMR, enables nurses to inform their colleagues about patients' emotions and feelings, fostering comprehensive and coordinated care. On a downside, nurses also admitted that interruptions caused by health technologies, such as nurse paging systems, can affect the emotional support provided by nurses.

Recognizing Patients With Limited Digital Health Literacy

In the interviews, nurses describe different practices to recognize a patient with limited digital health literacy, which could be divided into three categories: (1) intuition, (2) observation of verbal and nonverbal signals, and (3) explicitly ask and register in EMR (Table 5).

XSL•FO
RenderX

Table . Current practices in recognizing patients with limited (digital) health literacy.

Current practices and subthemes	Examples
Intuition	
Intuition	• Gut feeling, intuition
Observe verbal and nonverbal signals	
Patient characteristics	• Advanced age • Low educational level • Poor lifestyle • Comorbidities
Depending on network	• Social network • Care network
Behavior	• Non-compliant with advice • Not having a critical attitude • No motivation or not taking initiative • Asking less or irrelevant questions • Use of language: choice of words, writing style • Not understanding or not reading health information • Only using a few health technologies or difficulties with using them • Not willing to use health technologies • Excuses or avoiding information or do not want any information
Explicitly ask and register in EMR[a]	
Ask questions to identify limited digital health literacy	• Explicitly ask about digital skills and health literacy • Apply a validated assessment tool
Ask patients to demonstrate how they use health technologies	• Instructions are not carried out sufficiently • Ask the patient to demonstrate and observe difficulties
Register in the EMR	• Low literacy registered

[a]EMR: electronic medical record.

Intuition

One frequently used answer to the question on how nurses identify patients with limited (digital) health literacy was intuition. Twelve nurses mentioned that they use their gut feeling to assess if patients have limited or adequate (digital) health literacy. It was difficult for them to explain what this was based on, as is illustrated in the following quote: “You have a gut feeling that the patient is going to perform it properly, but on what do I base that ... I don’t know” (R3). Several nurses acknowledged that this nursing practice is quite uncertain and can lead to incorrect assessments.

Observe Verbal and Nonverbal Signals

Other nurses were more explicit about the cues they used for inferring limited literacy or digital literacy in their patients. Certain patient characteristics were mentioned, including advanced age, low educational level, multiple comorbidities, and an unhealthy lifestyle. Some of these characteristics were observed, such as being overweight, advanced age, smoking, and shabby clothing. Other characteristics were indirectly deduced, such as a low educational level and the presence of comorbidities.

Nurses also identify patients with limited digital health literacy based on the level of dependence on their social or care network. They either asked or observed during a hospital admission the extent to which patients rely on their family or acquaintances, for example, with reading or understanding health-related information or completing online questionnaires. Hospital nurses can collaborate with home care nurses or health care professionals from other departments to gather additional information of the patient.

Another nursing practice to identify patients with limited (digital) health literacy is by observing certain behaviors or verbal cues, such as lack of critical attitude, noncompliance with advice, asking irrelevant questions, and not being motivated. The following quote explains how a lack of a critical attitude is being used as a cue for limited (digital) health literacy:

> *I observe how critical a patient is, or whether he will let everything happen to him. For example, do they take their medication willingly, or do they ask me, what is it or what is it for? I take that into account in my assessment.* [R1]

Explicitly Ask and Register in EMR

Finally, nurses sometimes explicitly asked or assessed (digital) health literacy levels with questions or observed the patient while using the technology. An example of a question that was typically used by nurses to identify patients with limited health

XSL•FO
RenderX

literacy was as follows: “Do you feel overwhelmed by the abundance of health information?”

Digital skills were mostly identified with straightforward questions about the patients’ use of email, WhatsApp, or social media. Another nursing practice to identify limited digital literacy was to observe how a patient works with health technologies:

> *If we have the equipment on the ward to let them do it themselves and then I will observe them: How does the patient handle it, does the patient know how it works, what does someone do with the explanation? Does it then go right at once or does the patient need more frequent explanations? That does say something about the skills.* [R5]

Formal assessment tools to measure limited (digital) health literacy were never used, and most of the interviewed nurses did not know about the existence of such tools. During the interviews, it also became clear that low literacy is not or only scarcely registered in the EMR. Yet, several nurses indicated that it would be helpful to report about (digital) health literacy in the EMR to facilitate awareness and enable them to tailor care accordingly. Documentation in the EMR would also ensure that other involved health care providers would be informed so that the patient does not have to be repeatedly questioned about these skills.

Supporting Patients With Limited Digital Health Literacy

In daily practice, nurses use certain practices to support patients with limited (digital) health literacy in nursing care. Four main practices were identified: (1) create trust, (2) tailor communication, (3) provide additional support, and (4) use the patient network (Table 6).

Table . Current practices in supporting patients with limited (digital) health literacy.

Current practices	Subthemes
Create trust	• Create trust among patients in the health professional • Support the self-confidence of the patient • Normalize having limited (digital) health literacy
Tailor communication	• Repeat information • Limit the amount of information and use short explanations • Plain or easy language • Visualize • Use additional methods; write information down or use a whiteboard • Check if information given to the patient is understood (teach-back) • Step-by-step explanation • Clear instructions • Ask open questions • Develop tailored health technologies
Provide additional support	• More frequent contact (phone or face to face) • Provide a summary of the provided education and instructions • Create a place where patients can ask questions about the use of health technologies • Offer the nondigital method
Use the patient network	• Involving relatives to support the patient in using health technologies • Asking relatives to use health technology instead of the patient • When various relatives are receiving the information, relatives can also repeat it for the patient • If the patient does not understand the explanation, the nurse can use the patient’s network • Relatives can help the patients formulate questions • If no relative is available, arrange home care • Consult and coordinate with other caregivers

Create Trust

To support patients with limited (digital) health literacy, 5 nurses indicated that it is important to create trust. This practice included addressing patients’ distrust of health technologies, supporting and increasing patients’ self-confidence, and also creating trust in health professionals. Nurses mentioned that these are important skills to support patients in understanding health information and support patients in using health technologies. It is crucial to normalize having limited (digital) health literacy and inform patients that many patients are experiencing difficulties in understanding and applying (digital) health information. This was explained by one of the nurses as follows:

> *Some patients ask me, why are you asking if I can’t read? I always say, there are quite a lot of people in the Netherlands who cannot read at all. And if that is the case, we like to take that into account because then we can also show you information in a different way.* [R10]

XSL•FO
RenderX

Normalizing having limited (digital) health literacy hopefully contributes to less shame about having limited (digital) health literacy and makes it easier for the patient to ask questions or to indicate if something is not fully understood.

Tailor Communication

Different types of practices exist to tailor the communication to patients with limited (digital) health literacy. These include repeating information, using short explanations, using plain language, and visualizing information. Additional methods to support the patient's understanding of health information are to write down information or draw pictures and use a whiteboard in a hospital patient room. Certain nurses indicated using the teach-back method to ensure the patient's understanding. This method asks patients to state in their own words what they understood or remembered from the given health information [21]. Even though this method was mentioned, it was unclear whether all nurses performed it correctly, as several nurses subsequently indicated they were only asking if a patient still had any questions.

Provide Additional Support

Providing additional support is described as a useful nursing practice by the majority (n=16) of the nurses. An example was frequent telephone contact to establish more guidance and more opportunities to practice with health technology. Another suggestion was to create a support team who can be reached by phone, where patients can ask questions related to the use of health technologies.

In addition, nurses described that face-to-face communication instead of digital communication should remain possible, recognizing that not all patients may be capable of using health technologies even with extra support. Some nurses described that patients who were not willing or able to use health technologies were excluded from using health technologies. This means that these patients do not have the opportunity to participate and experience the positive effects of it. One nurse indicated that patients were never excluded from home dialysis, including the use of health technologies due to insufficient skills. Excluding none of the patients was a conscious decision, as long as the patient was willing to learn and try. Consequently, this requires nurses to invest time, patience, and creativity in guiding these patients.

Use the Patients' Network

The majority (n=15) of nurses reported that patients' social networks are also utilized to support patients with limited (digital) health literacy. For example, relatives can assist patients in working with health technologies and repeat important educational instructions: "But you can also check if the son, daughter, or grandchildren might know a little more about technology and could offer help" (R18). Besides, the health care network of a patient (eg, home care) can help if there are no relatives available. Consulting other caregivers about the care for the patient can lead to comprehensive care and appropriate support.

Barriers to Recognize and Support Patients With Limited (Digital) Health Literacy

Several barriers to recognize and support patients with limited (digital) health literacy exist. Regarding the work environment, one frequently mentioned barrier was the experienced workload. The continuous high workload often leaves limited time to identify patients with limited (digital) health literacy and provide tailored support. Moreover, nurses often see patients only for a very short time, which makes it particularly difficult to get to know the patient very well:

> *You don't know the patients when they enter the hospital and just being admitted. You have to get to know them first. That is sometimes difficult.* [R4]

Related to the patient, the nurse described that numerous patients feel ashamed about having limited (digital) health literacy and try to disguise this. This makes recognition more difficult. Another barrier is the family members who speak consistently on behalf of patients instead of giving the patient the opportunity to talk. This may make it difficult to gather the right information because it may be the opinion of the family rather than that of the patient. The last barrier is nurses' own lack of knowledge. Nurses indicate that they have little knowledge about recognizing and supporting these patients. As a result, they often rely on intuition.

Discussion

Principal Findings

The results of this study show that nurses in hospitals use a wide variety of health technologies, and this has affected the nurse-patient communication significantly, mainly in a positive way. Nurses mentioned intuition, observing verbal and nonverbal signals, and explicitly asking as nursing practices to identify patients with limited digital health literacy. Nursing practices to support patients with limited (digital) health literacy included building trust, tailoring communication, providing additional support, and engaging the patient's network. Several barriers were identified in recognizing and supporting patients with limited (digital) health literacy, including a high workload, lack of knowledge, and not knowing the patient.

Our results revealed that according to the nurses, health technologies affected all 6 functions of the de Haes and Bensing's communication model [2]. Positive consequences were seen in gathering and providing health information, enabling disease and treatment management, decision-making, and supporting patients to handle their emotions. These results are in line with previous research reporting benefits such as reduced unnecessary consultations, improved accessibility for patients, and the potential of messaging systems to facilitate nursing care [22. While our study primarily observed positive changes, we also identified certain challenges. These included, for example, verifying patients' understanding and addressing complex images or content that required additional explanation for patients. Similar challenges have been reported in other qualitative studies, including the additional workload associated with training patients [23]. These studies have further highlighted nurses' limited digital skills, as well as the rapid

XSL•FO
RenderX

pace of technology implementation [24]. Although overall changes were largely positive, it was notable that our study identified predominantly negative changes within the function of fostering the nurse-patient relationship. Similar challenges were reported in a study using focus groups with primary health care nurses exploring their views on eHealth tools for patient self-management [24]. Nurses expressed concerns about losing personal contact, perceiving digitalization as a potential threat to the nurse-patient relationship [24]. To overcome this challenge, nurses in our study recommended always starting with a face-to-face meeting and switching to digital communication only after the relationship is built. The preference for initial face-to-face consultations, as well as for combining digital and in-person consultations, has also been noted previously [25]. Our findings suggest that task-oriented functions of the 6-function model, such as providing health information and supporting disease management, benefit from technology through increased efficiency, accessibility, and structure. In contrast, relational functions, such as fostering the nurse-patient relationship, are harder to support digitally, as they rely on nonverbal cues and trust-building [2].

To the best of our knowledge, this study is the first to examine the impact of health technologies on nurse-patient communication using the 6-function model of communication [2]. Although the 6-function model was not specifically designed for use in the nurse-patient communication context, it proved to be highly usable, and nurses could easily relate to the 6 identified functions. This is in line with a previous study in which the model was used to examine nurse-patient communication [26]. Although the model was also not developed to study the impact of health technologies, it turned out to be helpful in providing insight into their impact on the various functions of communication.

In nurse-patient communication, it is important to identify the patients who experience difficulties in using health technologies. Patients with limited health literacy are less likely to use health technologies or perceive them as difficult and useless [27], while these patients can actually benefit from them, for example, from the visualization of health education through videos. To reduce exclusion of patients with limited (digital) health literacy, nurses can play a pivotal role in recognizing and supporting these patients. Nurses in our study mentioned different practices to recognize patients with limited (digital) health literacy. These are intuition, observed verbal and nonverbal signals, and explicitly asking patients about their (digital) health literacy skills or asking them to demonstrate the use of the health technology. Previous studies also showed that nurses often use their intuition to estimate health literacy [28] and use verbal and nonverbal cues, such as patients' use of simple language, facial expressions, or level of interaction [29]. Unfortunately, "intuition" and "observing verbal and nonverbal signals" are very subjective. Relying only on intuitions may not be an appropriate practice, since it is known that nurses frequently overestimate the health literacy of their patients [30]. Some verbal and nonverbal signals, such as lower education, low self-management, less motivation, and low self-efficacy, are indeed associated with limited (digital) health literacy [31,32], but this does not apply to every individual patient and may be difficult to observe. Moreover, for some nonverbal signals, such as looking slobby, evidence is lacking. A potentially more reliable nursing practice is to explicitly ask patients about their (digital) health literacy skills or to demonstrate how they use technology. Although the importance of this was acknowledged by a few of the interviewed nurses, it was not common practice. A reason for being hesitant to ask patients about their health literacy is that many patients feel ashamed about having limited (digital) health literacy [33]. Our results highlight the importance of educating nurses on how to assess patients' (digital) health literacy in a neutral and nonoffensive manner, so as to avoid causing discomfort or feelings of shame.

Interestingly, our results showed that patients' levels of (digital) health literacy are only occasionally documented in the EMR, despite the availability of numerous questionnaires to assess digital health literacy [34]. The systematic documentation of this information could reduce the need for repeated assessment and could enhance continuity of care among health care professionals within hospital settings.

To support patients with limited (digital) health literacy, nurses used different practices: building trust, tailoring communication, providing additional support, and engaging the patient's network. To tailor communication, the "teach-back method," already proven to be effective [21], was often mentioned. Unfortunately, it appears that the teach-back method is not always performed correctly. A recent review including similar health literacy practices as in our study showed positive effects on patient support, including activation, patient comprehension, and engagement [35]. Strategies often included multimedia or technology-based approaches, simplification of written material, and facilitation of in-person sessions. More research is needed to examine if these practices are actually effective and how nurses can be motivated to use these in daily practice.

Our study revealed that many nurses are experiencing multiple important barriers while recognizing and supporting these patients. These include a high workload, lack of knowledge, and not knowing the patient. For some of these barriers, training could be helpful. Training, encompassing various educational programs and online resources, has been identified as an effective intervention that significantly contributes to improving digital health literacy [36]. Several studies have shown that offering training for nurses on how to recognize and support patients with limited health literacy shows positive effects on knowledge, attitude, confidence, and increased usage of strategies to recognize and support patients with limited health literacy [37-43]. Unfortunately, the digital component is often not included (yet) in these existing training. It is recommended that nursing education and existing training programs systematically integrate the digital component, with particular emphasis on enabling nurses to recognize and support patients with limited (digital) health literacy.

Strengths and Limitations

A strength of this study is that a heterogeneous group of nurses from different wards and various specializations was included. This contributed to more generalizable results regarding nurses working in hospitals. This study was conducted in the Dutch hospital context, where the implementation of health

XSL•FO
RenderX

technologies is relatively advanced. However, it remains unclear how these findings translate to other countries, as differences in health care systems, digital developments, digital literacy of nurses, and organizational structures may influence the adoption and impact of health technologies. Further research in diverse international contexts is needed to explore their applicability beyond the Netherlands.

In this study, we selected participants who had at least some experience with health technologies to explore their perspectives based on actual use. As a result, our findings primarily reflect the experiences of nurses with some engagement in digital technologies. Future research including nurses with little or no prior experience could provide additional insights into potential barriers and challenges.

Future Research

Since this study primarily used self-reported data, it would be valuable to observe actual nursing behaviors in practice, for example, how frequently nurses use strategies to recognize and support patients with limited digital health literacy. Furthermore, gaining a deeper understanding of patients' perspectives is equally important. Patients with limited digital health literacy may experience challenges with health technologies that differ from or overlap with those faced by nurses. It is still unclear to what extent patients recognize potential disadvantages or barriers related to technology use. Therefore, future research should explore the specific difficulties patients encounter and the types of support they need to effectively engage with digital health tools.

Besides the patient perspective, future research may explore potential differences across hospital departments, as communication challenges may vary by clinical context. For example, nurses working in intensive care units may face distinct communication challenges, such as needing to communicate primarily with family members or navigating ethical considerations related to digital consent.

Providing training to nurses on how to support patients with limited (digital) health literacy could be beneficial. Such training may help nurses apply structured strategies rather than relying solely on intuition. When developing this training, it is important to cocreate its content with nurses from diverse clinical settings and with varying levels of experience, ensuring that the modules align with current practice. In addition, integrating these competencies into nursing education is essential so that future nurses also develop the necessary skills.

Moreover, involving nurses in the selection and implementation of health technologies is important. Their perspectives can guide the choice and adoption of new technologies, the design of training programs, and the development of user-friendly systems, such as EMRs. This approach helps ensure that digital health innovations are accessible, practical, and responsive to the needs of both nurses and patients. Ultimately, the impact of these technologies depends not only on the tools themselves but also on organizational and systemic factors, including staff readiness, training support, and supportive organizational structures [44-46].

Conclusions

This study shows that health technologies have strengthened nurse-patient communication and extended de Haes and Bensing's model [2] to the digital context. Yet, challenges persist, particularly in fostering relationships. It also reveals that systematic (digital) health literacy assessment remains lacking and that current practices to identify and support patients with limited (digital) health literacy may not always be effective. Once effective approaches are established, they should be integrated into nursing care plans and education.

Acknowledgments

We thank Alex Boshuizen and all students for their assistance in conducting this research and all nurses and nursing students for participating in this study.

Abstract

Background: The prevention of medical errors depends on effective communication and teamwork between nurses, yet traditional nurse call systems create inefficiencies that result in higher staff workloads. Further research is needed to evaluate how digital health care technologies affect nursing workflows and whether they contribute to staff workload.

Objective: This study aimed to evaluate whether a smartphone app using Bluetooth Low Energy (BLE) Mesh–based signal communication could enhance nurse-to-nurse communication, decrease response times, and improve teamwork as measured by the TeamSTEPPS Teamwork Perceptions Questionnaire (T-TPQ).

Methods: We conducted a between-subjects (independent groups) interventional study on an acute care ward, with 3 intervention days (BLE Mesh app use) and 3 nonintervention days administered on alternating days. Thirty nurses (15 per condition) participated, with no nurse contributing observations to both conditions in the final analysis. Response times were tracked, and the T-TPQ was used to evaluate Situation Monitoring and Mutual Support perceptions at the end of each shift.

Results: The app shortened the total response duration from a per-nurse median of 38.5 (IQR 31.0-58.5) seconds in the control condition to 19.5 (IQR 18.5-23.5) seconds in the intervention condition (n=15 per condition; Mann-Whitney *U* test=217.5; *P*<.001; rank-biserial *r*=–0.93). The app reduced the time it took for staff to confirm nursing actions, search for items, and request care assistance. A total of 40 nurses participated, generating 48 questionnaire responses; after exclusions, 30 nurses (15 per condition) were analyzed. T-TPQ confirmed significant improvements in Situation Monitoring (3.04 vs 3.39; *P*=.001) and Mutual Support (3.01 vs 3.31; *P*=.003). Post hoc power ranged from 87% to 92% (Cohen *d*>1.0), supporting the interpretability of these results.

Conclusions: BLE Mesh technology reduces basic signal communication delays, which shortens nurse response times and enhances team performance through improved Situation Monitoring and Mutual Support, according to our research. The study demonstrates how this technology delivers functional benefits that enhance nursing communication to produce superior team-based care outcomes.

nursing communication; teamwork; digital health; response time; mobile apps

Introduction

Effective communication and robust teamwork are foundational pillars of high-quality health care delivery, particularly within nursing practice. The intricate nature of patient care necessitates continuous, efficient, and accurate information exchange among health care professionals to ensure comprehensive and holistic patient outcomes [1]. This "professional communication" is paramount for facilitating information sharing, enhancing the appropriateness of medical interventions, and ultimately improving patient safety [2]. Conversely, communication failures represent a pervasive and critical issue in modern health care, frequently leading to medical errors, adverse events, and even preventable patient mortality [1-3]. Indeed, ineffective communication often creates obstacles to information flow among health care teams, a lack of teamwork, organizational inefficiencies, and decreased staff morale. Notably, poor communication has been identified as the sole cause in 13.2% of patient safety incidents and a contributing factor in 24.0% of incidents [4]. Factors such as hierarchical structures, cultural

XSL•FO
RenderX

differences, or even disruptive behaviors in the health care environment can hinder effective communication, highlighting the need for improvements through organizational commitment, training, and standardized policies [2]. This underscores the urgent necessity for innovative solutions to enhance communication and collaboration within health care teams.

Despite the recognized importance of effective communication, nurses frequently encounter significant challenges that impede seamless information transfer and mutual support. For example, traditional nurse call systems are predominantly static and "place-oriented," confining patients to fixed locations for initiating calls and lacking crucial contextual information regarding patient risk factors or staff availability [2,5]. This leads to considerable inefficiencies, including unnecessary interruptions for nurses, wasted time spent locating staff (≈10% of nursing time is spent "looking for someone"), and inappropriate call routing, where highly skilled registered nurses are often engaged in tasks outside their professional scope [2,5]. Such situations can increase nurses' workload and potentially diminish the quality of care.

Furthermore, while digital technologies are increasingly integrated into nursing practice with the aim of improving efficiency and communication, their impact is not always positive. The adoption of information and communication technologies, such as smartphones and wearable devices, indicates a tendency for nurses to use these tools for information retrieval and communication with health care team members. However, their overall impact on nurses' perceived workload has been complex, often proving "mainly negative" [6-8]. This suggests that simply introducing technology, without careful consideration of workflow integration and cognitive load, can inadvertently exacerbate existing burdens [5]. Barriers to the adoption of digital health technologies include infrastructural and technical issues, psychological and personal concerns, and worries about increased working hours and workload. Conversely, training, perceived usefulness, government incentives, and user involvement in development have been identified as facilitators for adoption [5].

Bluetooth Low Energy (BLE) Mesh is a communication solution characterized by its flexibility, reliability, and low power consumption. It offers the advantage of enhanced network coverage and internetwork connectivity, which is especially beneficial in complex hospital environments [8]. While BLE has seen applications in the medical field, such as for contact tracing and patient monitoring systems [8,9], research specifically focused on leveraging this technology for dynamic, peer-to-peer communication and mutual support among nurses, with an emphasis on concretely reducing workload and improving communication efficiency, largely remains unexplored. This app is characterized by simple signals conveying mutual support among nurses. Therefore, to address these significant gaps and challenges, this study developed and validated a novel, simple signal communication app using BLE Mesh network technology.

Methods

Study Design

This study used a between-subjects (independent groups) interventional design, comparing nurse response times (RTs) and teamwork perceptions between an intervention condition (using the BLE Mesh app) and a nonintervention condition (without the app), administered on alternating days. Different nurses participated in each condition; in the final analysis, no individual nurse contributed observations to both groups.

Intervention Design

This research comprises 2 distinct phases: intervention and nonintervention days administered on alternating days, beginning with a nonintervention day. The study included 3 app-use days alongside 3 app-free days for a complete observation period of 6 days.

Participants

Each shift on the ward was staffed by approximately 8 room-based nurses, including the charge nurse, who shared primary responsibility for direct patient care. Because nurses were assigned to shifts according to the standard ward roster rather than being fixed across the study period, a total of 40 unique nurses participated across the 6 study days, generating 24 questionnaire responses per condition (48 responses in total). Different nurses contributed to the intervention and nonintervention conditions, and those who happened to provide responses under both conditions were excluded from the final analysis (see "Demographic Data" section).

Experimental App

This study developed a prototype smartphone app as research support for social signal communication between nurses. Through its core technology, the app builds a mesh network using BLE to allow real-time communication between multiple devices. Users can access the app through smartphones running Android OS (Android 11 or later) with dynamic mesh network configurations. The study used 8 Google Pixel 4a devices running Android 13. The app functions through 2 different call systems that distinguish between critical and nonurgent assistance needs: green call and red call. In green call, the function is intended for nonemergency help requests. The app communicates both call types and sender names to the other nurses' terminals when a user initiates a call. The call is cleared when any recipient presses the designated response button; a confirmation notice is then displayed for 20 seconds on the sender's terminal (10 s on the other terminals). In red call, the function serves as an urgent help request system. The notification persists until 2 responders answer the call or the initiator manually ends the alert.

The app was developed as a research prototype by the study team. The Android app was built using Android Studio (Google LLC) and implements a custom application-layer BLE relay protocol, enabling multihop, infrastructure-free, device-to-device communication. Message delivery was subjectively immediate in prestudy testing, although formal latency measurements were

XSL•FO
RenderX

not performed. The prototype underwent iterative usability testing by the research team prior to deployment.

Experimental Procedure and Data Collection

The nurses who participated in the study received Android devices with the app they needed to complete for this research. The data collection process included both days with app use and days without app use according to the following framework:

- Preliminary explanation and informed consent: the study's objective, along with its details, privacy measures, and ethical principles, was presented verbally and in writing to obtain consent.
- Observation during work shift (6 h): participants' actions were observed during their 6-hour work shift.
- Intervention day: the developed app was used.
- Nonintervention day: the app was not used; participants only carried the device.
- Postshift evaluation: after the work shift, participants answered a questionnaire regarding teamwork perception. The observation of cooperative actions was conducted by observers with nursing qualifications.

Evaluation Items

This research investigates the clinical impact of app use by evaluating the time taken for responses to occur as its main outcome.

Method of Measuring RT

The RT measurement procedure operates identically for both intervention days and nonintervention days. The observer starts timing when the nurse expresses their intention to contact another staff member. The observed period ends when the nurse initiates a work-related dialog with another person, which marks the end of the RT interval.

Measurement Scales

The Agency for Healthcare Research and Quality created TeamSTEPPS Teamwork Perceptions Questionnaire (T-TPQ) [10] as a research-based framework for enhancing team performance to improve health care quality and safety [11], and T-TPQ has already been validated in many languages, including Japanese [12-14]. The T-TPQ consists of 35 self-report items that assess individual perceptions about the 5 core competencies: Team Structure, Leadership, Situation Monitoring, Mutual Support, and Communication [15]. This study focused on the Situation Monitoring and Mutual Support competency scales from the T-TPQ because these 2 dimensions are most directly relevant to the intervention mechanism. Situation Monitoring captures nurses' awareness of their team members' statuses and the surrounding environment, which is directly facilitated by the app's real-time broadcast notifications. Mutual Support captures assistance-seeking and assistance-offering behaviors, which are directly targeted by the app's Green Call and Red Call functions. The remaining 3 T-TPQ competencies (Team Structure, Leadership, and Communication) were considered less directly addressed by this simple signal-based intervention and were therefore excluded from the primary analysis.

Data Analysis

All statistical analyses were performed using IBM SPSS Statistics and Python (*statsmodels*; Python Software Foundation).

Primary Analysis (RT)

The prespecified primary analysis compared per-nurse median RTs between the 15 control and 15 intervention nurses using a 2-sided Mann-Whitney *U* test (exact test). Each nurse's RT events were first aggregated into a single per-nurse median, yielding the 15-vs-15 comparison and bringing the RT analysis into structural symmetry with the T-TPQ analysis (which is inherently per-nurse).

Sensitivity Analyses (RT)

Two prespecified sensitivity analyses on the unaggregated event-level data were performed using linear mixed effects models on log-transformed RT, fitted by restricted maximum likelihood: (model A) log(RT)~Condition+(1 | nurse; Table S1 in Multimedia Appendix 1) and (model B) log(RT)~Condition+(1 | day; Table S2 in Multimedia Appendix 1).

Exploratory Analysis (RT by Request Category)

Event-level Mann-Whitney *U* tests were applied within each of the 6 request categories. Per-nurse aggregation within each category was not used because each nurse contributed only 0 to 3 events per category. To control the family-wise error rate across the 6 categories, a Bonferroni correction was applied (adjusted α=.05/6≈.0083).

T-TPQ Analysis

The Mann-Whitney *U* test (2-sided, with normal approximation and continuity correction) was applied at the per-nurse level (n=15 per condition) to the total subscale scores for Situation Monitoring and Mutual Support and the 7 individual item scores within each subscale. Subscale-total comparisons were treated as single confirmatory tests and were, therefore, not Bonferroni-adjusted. Item-level tests within each subscale were Bonferroni-adjusted across 7 items (α=.05/7≈.0071).

Effect Sizes and Power

Effect sizes were quantified using Cohen *d* on the log scale and rank-biserial *r*. Post hoc power was estimated at α=.05.

Sample Size Calculation

To our knowledge, no prior study has evaluated the effect of BLE Mesh–based real-time communication systems on nurse RT or teamwork perceptions. The absence of equivalent preceding research meant that no empirical basis existed for estimating the expected effect size, and accordingly, a formal a priori sample size calculation was not conducted. The study was designed as a feasibility investigation to generate preliminary effect size estimates that can inform the sample size planning of future adequately powered trials. Post hoc power analysis was, therefore, conducted to retrospectively assess whether the achieved sample provided adequate power to detect the observed effects.

Ethical Considerations

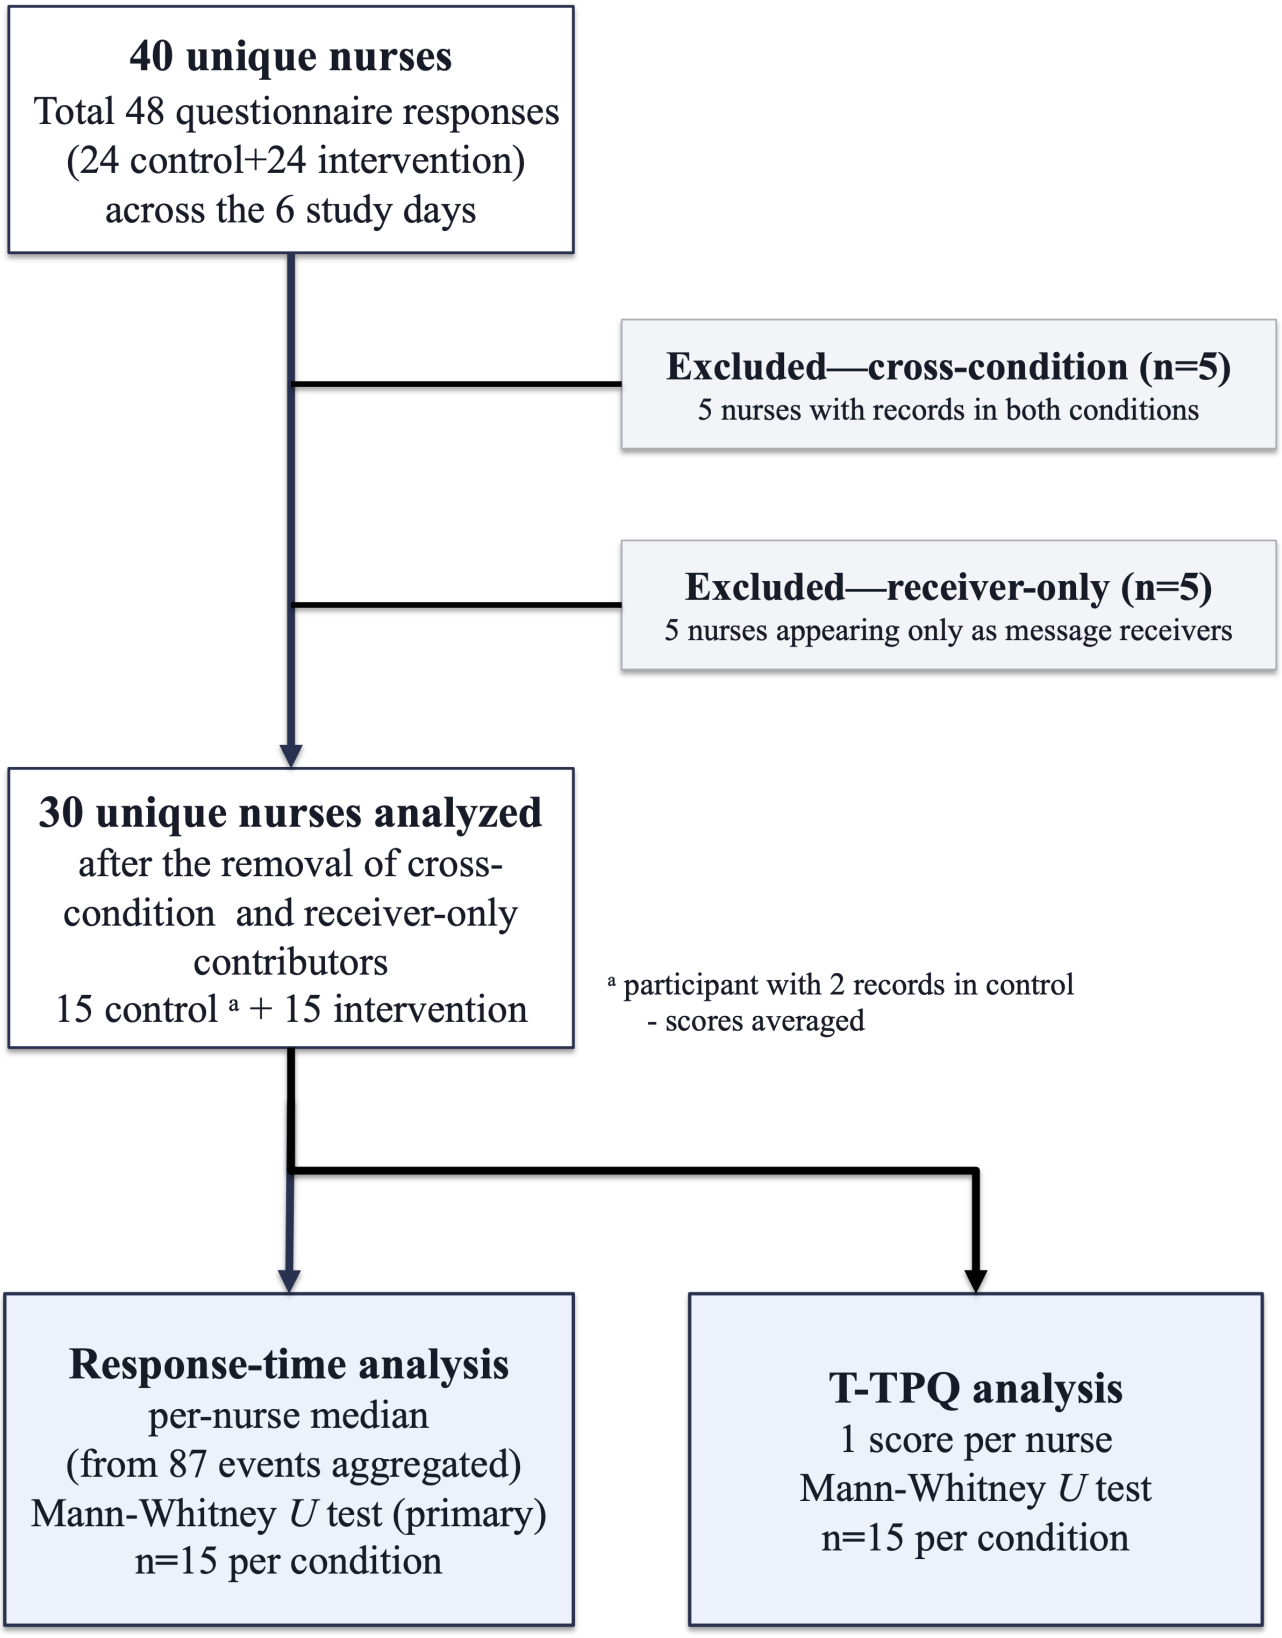
The study was approved by the University of Tsukuba Institutional Review Board (approval 2024R885) and was conducted in accordance with principles equivalent to those of the Declaration of Helsinki. Consent for participation and data use was obtained through an opt-out procedure approved by the institutional review board. A written notice describing the study objectives, the types of data to be recorded, the data protection procedures, and the procedure for declining participation was posted in the ward in advance, and nurses who did not opt out during the notification period were considered to have consented to participation. In addition, prior to each observation session, the research team provided a careful verbal explanation of the study objectives, the data to be recorded, and each participant's right to decline or withdraw at any time, giving every on-duty nurse repeated opportunities to ask questions or withdraw before the session began. To protect staff privacy, nurse identifiers in the behavioral logs and questionnaire records were replaced with pseudonymous participant IDs at the time of data entry; the linkage table was stored separately on an access-controlled institutional server and was not exported with the analysis files. Communication logs recorded only (1) the time interval between request initiation and response, (2) the request location at the room level (not patient identifier), and (3) the request category; no patient identifiers, patient clinical data, or patient outcomes were recorded. Questionnaire responses were collected in a manner that did not link individual respondents to specific patients. Access to raw logs and questionnaire data was restricted to the research team.

Results

Demographic Data

A total of 48 questionnaire responses were collected from 40 unique nurses: 24 responses under the nonintervention condition and 24 under the intervention condition. Because some nurses responded more than once, the following screening steps were applied to ensure unique samples.

First, 5 nurses who participated in both the intervention and nonintervention conditions were excluded to avoid within-subjects contamination, leaving 35 nurses who participated in only 1 condition (18 in the nonintervention group and 17 in the intervention group).



Second, 5 nurses (3 from the nonintervention group and 2 from the intervention group) were excluded because they appeared only as message receivers in the behavioral log and contributed no sender-initiated data, making it impossible to link their questionnaire responses to observed cooperative behaviors.

Finally, 1 nurse, who submitted 2 responses within the nonintervention condition, had the scores averaged to produce a single record.

These steps yielded 15 unique participants per condition (30 total; Figure 1).

RenderX

Observed Requests

These 30 participants collectively initiated a total of 87 requests (38 under the control condition and 49 under the intervention condition) across the 6 days of study.

The nonintervention group (control group) made 38 requests, while the intervention group submitted 49 requests. As shown in Table 1, the locations of the requests in the control group (n=38) comprised 13 (34%) requests from 4-bed room, 14 (37%) requests from corridor, 5 (13%) requests from nurse station, 3 (8%) requests from private room, and 3 (8%) requests from day space.

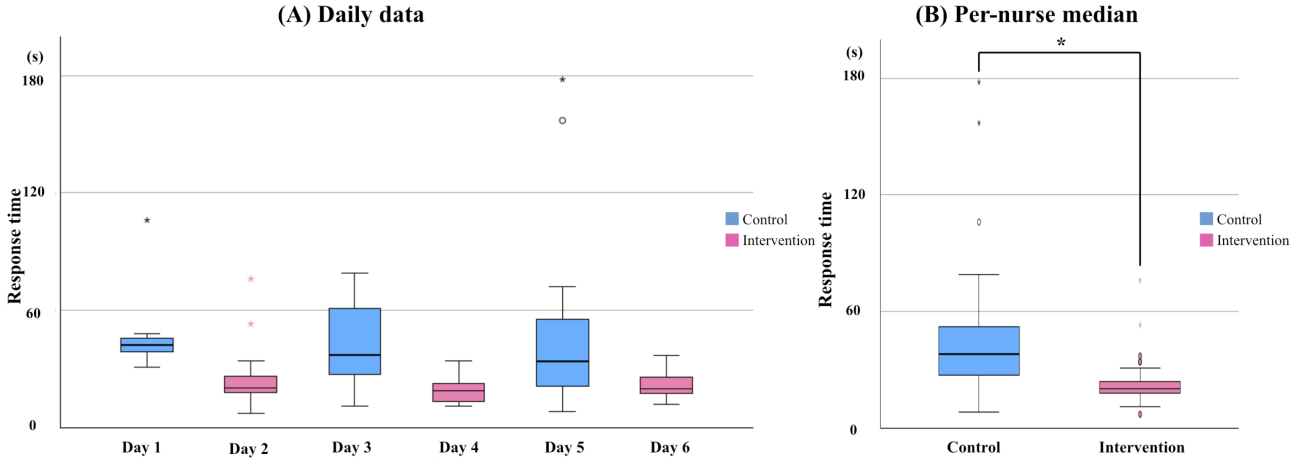
The intervention group (n=49) obtained 22 (45%) requests from the 4-bed room, 12 (24%) requests from corridor, 14 (29%) requests from nurse station, 1 (2%) request from private room, and 0 (0%) requests from day space.

The control group (n=38) included 11 (29%) requests for information sharing, 9 (24%) requests for confirmation to nurse, 8 (21%) requests for care help, 4 (11%) requests for consultation, 4 (11%) requests for inquiry for items, and 2 (5%) requests for confirmation to leader. On the other hand, in the intervention group (n=49), there were 12 (24%) requests for information sharing, 12 (24%) requests for confirmation to nurse, 8 (16%) requests for care help, 11 (22%) requests for consultation, 4 (8%) requests for inquiry for items, and 2 (4%) requests for confirmation to leader.

All observed nurse-initiated requests were classified by the on-site observer into 1 of 6 content categories at the time of each interaction. Care help refers to requests for direct physical assistance with patient care tasks such as repositioning, lifting, or procedural support. Consultation refers to requests for clinical advice or peer consultation regarding patient management decisions. Information sharing refers to the proactive communication of patient-related updates or clinically relevant information to colleagues. Confirmation to nurse refers to requests for verification or acknowledgment from a peer nurse regarding an observation, a procedure, or a care plan. Inquiry for items refers to requests for assistance in locating medical equipment or supplies. Confirmation to leader refers to requests directed to the charge nurse for guidance, approval, or supervisory input.

Table . Number of requests by category per study condition.

Variable	Control (n=38)	Intervention (n=49)
Count of request, n (%)		
Day 1 (control)	8 (21)	—[a]
Day 2 (intervention)	—	21 (43)
Day 3 (control)	18 (47)	—
Day 4 (intervention)	—	12 (24)
Day 5 (control)	12 (32)	—
Day 6 (intervention)	—	16 (33)
Location of request, n (%)		
4-bed room	13 (34)	22 (45)
Corridor	14 (37)	12 (24)
Nurse station	5 (13)	14 (29)
Private room	3 (8)	1 (2)
Day space	3 (8)	0 (0)
Category of request, n (%)		
Information sharing	11 (29)	12 (24)
Confirmation to nurse	9 (24)	12 (24)
Care help	8 (21)	8 (16)
Consultation	4 (11)	11 (22)
Inquiry for items	4 (11)	4 (8)
Confirmation to leader	2 (5)	2 (4)



[a]Not applicable.

Primary Analysis: Per-Nurse RT

As the primary analysis, RT observations from the 3-day intervention period and the 3-day nonintervention period were first aggregated to a per-nurse median to account for the within-nurse clustering of repeated observations. The resulting 15 control values and 15 intervention values were then compared using a 2-sided Mann-Whitney *U* test. Daily medians of the unaggregated event-level data are shown in Figure 2 for reference.

XSL•FO
RenderX

Figure 2. Impact of app use on nurse response times: daily intervention and control data. (A) Event-level response times for each of the 6 study days (boxplots: median, IQR, whiskers) and the corresponding daily medians shown in the accompanying table. (B) Per-nurse median response times for the 15 control and 15 intervention nurses, which constitute the primary analysis; the intervention condition significantly reduced response time (Mann-Whitney *U* test=217.5; *P*<.001; rank-biserial *r*=−0.93, large effect). The asterisk symbol (*) in panel (B) denotes a statistically significant difference between the control and intervention conditions (Mann-Whitney *U* test; *P*<.001).

	Day 1	Day 2	Day 3	Day 4	Day 5	Day 6
Time (s), median (IQR)	42 (40-44)	20 (18-26)	37 (28-59)	19 (14-22)	34 (21-47)	20 (18-25)

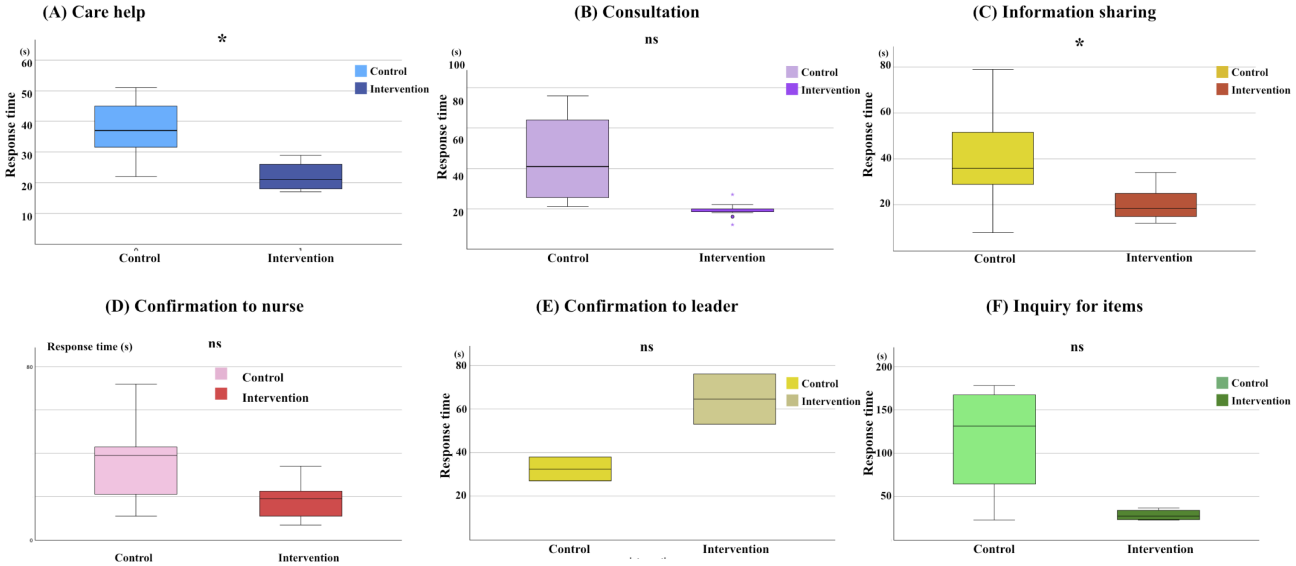
	Control	Intervention	*P* value
Time (s), median (IQR)	38.5 (31-58.5)	19.5 (18.5-23.5)	<.001

○, outlier (1.5–3 box lengths); plot-area *, extreme outlier (>3 box lengths). Symbol colors indicate study condition only.

The median (IQR) of daily RTs is shown in Figure 2 as follows: day 1 (control) was 42 (IQR 40-44) seconds, day 2 (intervention) was 20 (IQR 18-26) seconds, day 3 (control) was 37 (IQR 28-59) seconds, day 4 (intervention) was 19 (IQR 14-22) seconds, day 5 (control) was 34 (IQR 21-47) seconds, and day 6 (intervention) was 20 (IQR 18-25) seconds.

At the per-nurse level, the median RT was 38.5 (IQR 31.0-58.5) seconds in the control condition and 19.5 (IQR 18.5-23.5) seconds in the intervention condition. The difference was statistically significant (Mann-Whitney *U* test=217.5; *P*<.001; rank-biserial *r*=–0.93, large effect).

Sensitivity Analysis: Linear Mixed Effects Model



To formally account for the within-nurse clustering of repeated observations, a prespecified sensitivity analysis fitted a linear mixed effects model to all 87 events with log-transformed RT as the outcome, condition as a fixed effect, and a random intercept for nurse (Table S1 in Multimedia Appendix 1). The intervention reduced log-transformed RT by β of −0.67 (95% CI −0.93 to −0.41; *P*<.001), corresponding to a 48.7% reduction in geometric mean RT. The within-nurse intraclass correlation of 0.14 was modest, indicating that the per-nurse aggregation used in the primary analysis provides an interpretable summary, while the mixed effects model formally confirms the result under the residual within-nurse correlation.

Exploratory Analysis: RT by Request Category

As an exploratory analysis, event-level RTs were compared between conditions within each of the 6 request categories using 2-sided Mann-Whitney *U* tests (Figure 3). To control the family-wise error rate across the 6 categories, Bonferroni correction was applied (adjusted α=.05/6≈.0083). Two categories remained significant after correction: “Care help” decreased from 37 (control) to 21 seconds (intervention; *P*=.003) and “Information sharing” decreased from 36 to 18.5 seconds (*P*=.006). Two further categories showed nominal reductions of similar magnitude but did not survive Bonferroni correction: “Consultation” (41-20 s; *P*=.01) and “Confirmation to nurse” (39-19 s; *P*=.02). “Inquiry for items” showed a numerically large reduction from 131.5 to 27.5 seconds that did not reach statistical significance (*P*=.25). For “Confirmation to leader,” median values were 32.5 seconds (control; n=2) and 64.5 seconds (intervention; n=2); with only 2 observations per condition, this comparison was underpowered (*P*=.25) and should be interpreted with caution.

Figure 3. Impact of app use for category of request. Boxplots show the median response time (IQR values) for each of the 6 request categories under the control and intervention conditions, with per-category Mann-Whitney *U* test values and *P* values listed in the accompanying tables. Bonferroni correction was applied across the 6 categories (adjusted α=.05/6≈.0083). Care help (*P*=.003) and information sharing (*P*=.006) remained significant after correction; consultation (*P*=.01) and confirmation to nurse (*P*=.02) showed nominal reductions that did not survive correction; Inquiry for items (*P*=.25) and confirmation to leader (*P*=.25) did not differ between conditions. ns: not significant.

*** Significant after Bonferroni correction across the 6 per-category Mann-Whitney *U* tests (α=.05/6≈.0083).**

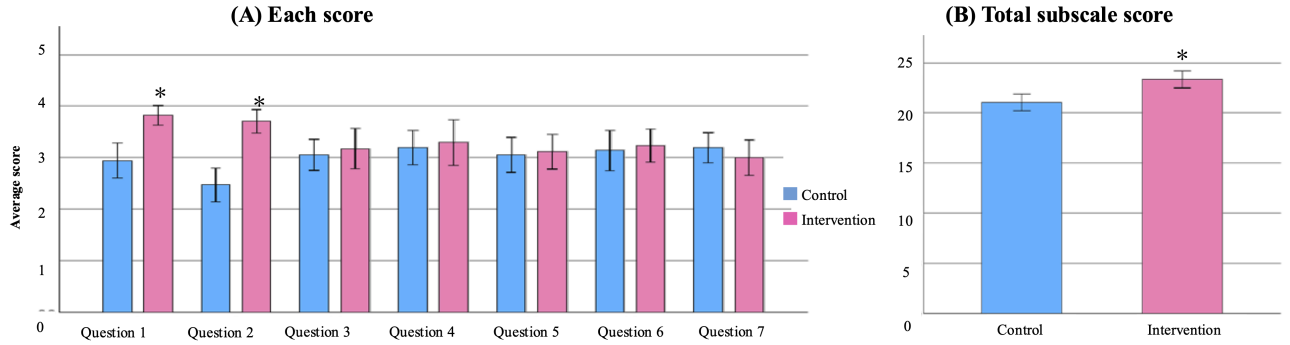
Effect on Perceived Situation Monitoring (T-TPQ)

T-TPQ results were analyzed using the Mann-Whitney *U* test on 30 unique participants (n=15 per condition) identified from sender activity logs. For Situation Monitoring, the Mann-Whitney *U* test was applied to check for significant differences between individual T-TPQ items, with a Bonferroni-adjusted α of .0071. As shown in Figure 4, 1 item reached statistical significance after correction: question 2, “Staff monitor each other’s performance” increased from 2.70 (control) to 3.93 (intervention); *P*<.001 (significant, large effect). The remaining 6 items did not reach significance: question 1, “Staff effectively anticipate each other’s needs” (control 2.87 vs intervention 3.27; *P*=.13); question 3, “Staff exchange relevant information as it becomes available” (3.20 vs 3.53; *P*=.44); question 4, “Staff continuously scan the environment for important information” (*P*=.29); question 5, “Staff share information regarding potential complications (eg, patient changes, bed availability)” (3.37 vs 3.20; *P*=.68); question 6, “Staff meet to reevaluate patient care goals when aspects of the situation have changed” (2.77 vs 3.33; *P*=.07); and question 7, “Staff correct each other’s mistakes to ensure that procedures are followed properly” (3.17 vs 3.00; *P*=.54). The Situation Monitoring total score improved from a mean of 3.04 (SD 0.39) in the control group to 3.39 (SD 0.19) in the intervention group (Figure 4), and the difference was statistically significant (*P*=.001; Cohen *d*=1.13, large effect).

XSL•FO
RenderX

Figure 4. Impact of the intervention on perceived Situation Monitoring (TeamSTEPPS Teamwork Perceptions Questionnaire domain). (A) Average score for each of the 7 Situation Monitoring items (Question 1-Question 7) under the control and intervention conditions (error bars represent the SE). (B) Total subscale score (sum across Question 1-Question 7). Item-level Mann-Whitney *U* tests were Bonferroni-adjusted across the 7 items (α=.05/7≈.0071); the subscale-total comparison was a single confirmatory test and was, therefore, not Bonferroni-adjusted. The total subscale score improved significantly under the intervention condition (3.04 to 3.39; *P*=.001; Cohen *d*=1.13, large effect). At the item level, Question 2 ("Staff monitor each other's performance") was the only item that survived Bonferroni correction (*P*<.001). Asterisks (*) denote items significant comparisons: in panel (A), the item that survived Bonferroni correction (question 2; *P*<.001; Bonferroni-adjusted α=.05/7≈.0071); in panel (B), the significant confirmatory subscale-total comparison (*P*=.001; not Bonferroni-adjusted, as prespecified).

Situation Monitoring	Intervention, mean (SD)	Control, mean (SD)	*P value*	Cohen *d*	Bonferroni-adjusted[a]
Total subscale score	23.73 (1.33)	21.30 (2.72)	.001	1.13	Significant
1. Staff effectively anticipate each other's needs	3.27 (0.59)	2.87 (0.74)	.13	0.59	Not significant
2. Staff monitor each other's performance	3.93 (0.26)	2.70 (0.80)	<.001	2.08	Significant
3. Staff exchange relevant information as it becomes available	3.53 (0.52)	3.20 (0.94)	.44	0.44	Not significant
4. Staff continuously scan the environment for important information	3.47 (0.74)	3.23 (0.68)	.29	0.33	Not significant
5. Staff share information regarding potential complications (eg, patient changes, bed availability)	3.20 (0.94)	3.37 (0.90)	.68	−0.18	Not significant
6. Staff meet to reevaluate patient care goals when aspects of the situation have changed	3.33 (0.90)	2.77 (0.68)	.07	0.71	Not significant
7. Staff correct each other's mistakes to ensure that procedures are followed properly	3.00 (0.76)	3.17 (0.84)	.54	−0.21	Not significant



a Bonferroni-adjusted: α=.007 (.05/7); Cohen *d*: 0.2=small, 0.5=medium, and 0.8=large

Effect on Perceived Mutual Support (T-TPQ)

As shown in Figure 5, for Mutual Support, 2 items reached statistical significance after Bonferroni correction: question 1, "Staff assist fellow staff during high workload," increased from 3.00 (control) to 3.80 (intervention), *P*=.003 (significant); question 2, "Staff request assistance from fellow staff when they feel overwhelmed," increased from 2.43 to 3.67, *P*<.001 (significant, large effect). The remaining 5 items did not reach significance: question 3, "Staff caution each other about potentially dangerous situations" (3.07 vs 3.20; *P*=.55); question 4, "Feedback between staff is delivered in a way that promotes positive interactions and future change" (3.30 vs 3.20; *P*=.98); question 5, "Staff advocate for patients even when their opinions conflict with those of a senior member" (2.93 vs 3.13; *P*=.46); question 6, "When staff have a concern about patient safety, they challenge others until they are sure the concern has been heard" (3.10 vs 3.13; *P*=.98); and question 7, "Staff resolve their conflicts, even when the conflicts have become personal" (3.23 vs 3.07; *P*=.49). The Mutual Support total score improved from a mean of 3.01 (SD 0.24) in the control group to 3.31 (SD 0.25) in the intervention group, as shown in Figure 5, and the difference was highly significant (*P*=.003; Cohen *d*=1.24, large effect).

XSL•FO
RenderX

Figure 5. Impact of the intervention on perceived Mutual Support (TeamSTEPPS Teamwork Perceptions Questionnaire domain). (A) Average score for each of the 7 Mutual Support items (Question 1-Question 7) under the control and intervention conditions (error bars represent the SE). (B) Total subscale score (sum across Question 1-Question 7). Item-level Mann-Whitney *U* tests were Bonferroni-adjusted across the 7 items (α=.05/7≈.0071); the subscale-total comparison was a single confirmatory test and was, therefore, not Bonferroni-adjusted. The total subscale score improved significantly under the intervention condition (3.01 to 3.31; *P*=.003; Cohen *d*=1.24, large effect). At the item level, 2 items survived Bonferroni correction: Question 1 ("Staff assist fellow staff during high workload"; *P*=.003) and Question 2 ("Staff request assistance from fellow staff when they feel overwhelmed"; *P*<.001). Asterisks denote items significant comparisons: in panel (A), the items that survived Bonferroni correction (question 1, *P*=.003; question 2, *P*<.001; Bonferroni-adjusted α=.05/7≈.0071); in panel (B), the significant confirmatory subscale-total comparison (*P*=.003).

Mutual Support	Intervention, mean (SD)	Control, mean (SD)	*P value*	Cohen *d*	Bonferroni-adjusted[a]
Total subscale score	23.20 (1.74)	21.07 (1.71)	.003	1.24	Significant
1. Staff assist fellow staff during high workload	3.80 (0.41)	3.00 (0.76)	.003	1.31	Significant
2. Staff request assistance from fellow staff when they feel overwhelmed	3.67 (0.49)	2.43 (0.62)	<.001	2.20	Significant
3. Staff caution each other about potentially dangerous situations	3.20 (0.77)	3.07 (0.59)	.55	0.19	Not significant
4. Feedback between staff is delivered in a way that promotes positive interactions and future change	3.20 (0.94)	3.30 (0.59)	.98	−0.13	Not significant
5. Staff advocate for patients even when their opinions conflict with those of a senior member of the unit	3.13 (0.74)	2.93 (0.70)	.46	0.28	Not significant
6. When staff have a concern about patient safety, they challenge others until they are sure the concern has been heard	3.13 (0.64)	3.10 (0.81)	.98	0.05	Not significant
7. Staff resolve their conflicts, even when the conflicts have become personal	3.07 (0.70)	3.23 (0.68)	.49	−0.24	Not significant

a Bonferroni-adjusted: α=.007 (.05/7); Cohen *d*: 0.2=small, 0.5=medium, and 0.8=large.

Discussion

Effects on Teamwork Perceptions (T-TPQ)

This intervention study was conducted with adequate statistical power across all primary outcomes. Post hoc power analyses confirmed that the achieved sample yielded 90% power for the overall RT outcome (Cohen *d*=1.19), 87% power for Situation Monitoring (Cohen *d*=1.13), and 92% power for Mutual Support (Cohen *d*=1.24), all exceeding the conventional 80% threshold. The findings discussed below are, therefore, considered robust within the scope of this single-site intervention study.

The minimal interaction communication app developed in this study, which uses BLE Mesh network technology, has been shown to be extremely effective in streamlining communication and improving teamwork among nurses. The intervention resulted in a significant reduction in overall RT and a significant improvement in the T-TPQ scores for both Situation Monitoring and Mutual Support. These results strongly suggest that this app can be a practical solution to communication challenges in the nursing field.

The most significant factor in the overall reduction in RT in this study is considered to be the transformation of the communication style itself: from making voice calls to specific individuals to being able to send a brief help signal to the whole team at once, without speaking, when assistance is needed. This way of sending a quick signal to the whole team without speaking streamlined operations through different mechanisms, depending on the nature of the task.

Among the 6 request categories, the most robust improvements—those that survived Bonferroni correction across the 6 per-category comparisons (adjusted α=.0083)—were observed for "Care help" (37-1 s; *P*=.003) and "Information sharing" (36-18.5 s; *P*=.006). For "Care help," assistance can typically be rendered by any available nurse with the requisite physical capacity, and sending the same signal to the whole team at once enabled instant access to the team's collective availability, reducing the time cost of locating a willing helper. For "Information sharing," sending the same signal to the whole team at once allowed clinically relevant updates to reach the team without interrupting the work of a specific recipient: a single signal reaches every team member at once, rather than being relayed from 1 nurse to the other.

Two additional categories—"Consultation" (41-20 s; *P*=.01) and "Confirmation to nurse" (39-19 s; *P*=.02)—showed nominal reductions of comparable magnitude but did not survive Bonferroni correction for multiple comparisons across the 6 categories. These results are best interpreted as hypothesis-generating: they are directionally consistent with the broadcast mechanism described above (ie, requests that can be fulfilled by any qualified peer rather than by a specific individual), but the present feasibility sample lacks the statistical resolution to confirm independent effects in these subcategories. The nonsignificant change in "Inquiry for Items" (131.5-27.5

XSL•FO
RenderX

s; *P*=.25), despite a numerically large median reduction, is likewise underpowered owing to the small per-category sample (n=4 per condition).

On the other hand, the limitations of this model were also revealed by the results for "Confirmation to leader." RT did not improve in this category alone because the request was directed to a specific individual in the team who had an irreplaceable role. In this case, the issue was not the time it took to find the leader but securing the leader's availability to respond, a problem that could not be solved by a simple broadcast. This is related to the busyness and digital stress of leadership positions, as pointed out by Laukka et al [16], and suggests that the technology to be introduced should be optimized according to the nature of the problem to be solved.

Overall, these category-level patterns are consistent with the broadcast mechanism described above.

The T-TPQ served as the assessment tool to measure teamwork perception changes, which showed substantial improvements in both the Situation Monitoring and Mutual Support categories. The app's real-time notification system, which makes each staff member's current situation visible to the rest of the team, likely caused the improvement in Situation Monitoring scores by giving every nurse the same picture of where each colleague is and what each is doing. The Mutual Support score improvement stands as a crucial discovery from this research. The literature shows that measuring Mutual Support in nursing teams becomes difficult because of the difference between staff-provided assistance and staff-received assistance. The app successfully reduced psychological barriers to help requests, according to our findings, which show substantial improvements in "Staff assist fellow staff during high workload" and "Staff request assistance from fellow staff when they feel overwhelmed." The decreased barriers enabled staff members to request help without hesitation, while available staff members provided support voluntarily, thus solving the problem identified in previous studies [17].

On the other hand, no significant difference was observed in items requiring more complex and advanced communication, such as "Staff caution each other about potentially dangerous situations" and "Staff resolve their conflicts." This indicates that while the app contributes to providing an "impetus" for and "streamlining" communication, it does not guarantee the content or quality of the interaction itself. Among individual Situation Monitoring items, question 1 ("Staff effectively anticipate each other's needs") and question 3 ("Staff exchange relevant information as it becomes available") did not reach statistical significance (*P*=.13 and *P*=.44, respectively). Critically, the overall subscale totals for both Situation Monitoring and Mutual Support were significant (*P*=.001 and *P*=.003, respectively), with large effect sizes (Cohen *d*=1.13 and 1.24), supporting the robustness of the primary findings.

Previous research shows that even a simple, content-light signal can convey complex and rich meaning when senders and receivers share an existing working relationship, along with the social, cultural, and emotional context that comes with it [18]. This experiment used these brief team-wide signals—sent without speaking, to the whole team at once—as an example of how a short, content-light signal can still convey rich meaning when the people involved share the clinical context. Because senders and receivers already share the same ward context, a short signal can carry several layers of meaning, and meaningful cooperative behavior becomes possible with very little explicit content. The results show that what matters is not the amount of information carried by the signal, but the depth of interpretation that the professionals on each end of the signal bring to it.

Minimal communication should, therefore, be viewed not as a limitation but as a starting point that draws on the nurses' interpretive skills, builds on their working relationships, and uses their clinical experience to produce a shared understanding.

The result of this study suggests that successful outcome is determined not only by the superiority of the technology itself but also by how it is accepted and used in the field. Livesay et al [19] point out that a major reason for the failure of digital health adoption is the lack of nurse involvement in the design and implementation process, as well as inadequate training, indicating that technology lacking a field perspective can disrupt workflows. Furthermore, Fitzpatrick [20] warns of the overlooked negative aspect of digitalization, where the increase in communication volume can, conversely, contribute to health care provider burnout. Additionally, the adoption rate among staff can be an issue in this type of technology implementation. For example, in a contact tracing study by Curtis et al [21], the participation rate, especially among physicians, was reported to be low despite the use of anonymous tags, possibly due to privacy concerns. The key to the success of these technological innovations lies in the close collaboration between nurses, who have a deep understanding of the nursing field, and researchers and developers in the engineering field. Wang et al [22] emphasize that deep collaboration between nursing professionals and Internet of Things technology developers is essential for the effective implementation of these technologies. It should also be acknowledged that this study evaluated teamwork perceptions using only 2 of the 5 T-TPQ subscales, and that self-report questionnaire data had inherent limitations in capturing the full complexity of team processes. Perceptual scores reflect nurses' subjective appraisals and may be susceptible to response bias or social desirability effects. Objective behavioral measures of teamwork, such as structured observational coding or interaction analysis, would complement the self-report data in future studies. Furthermore, the 3 T-TPQ subscales not assessed in this study (Team Structure, Leadership, and Communication) may also have been influenced by the intervention in ways not captured here, and future research should consider comprehensive multidimensional teamwork assessments. Only when digital health is built on the needs of the clinical floor and keeps the nurses who actually use it firmly in view can it achieve its ultimate goal of improving the quality and safety of health care [19-25].

Limitations

This study has several limitations, including a small sample size of 8 nurses per shift at a single acute care ward; a short study

XSL•FO
RenderX

period of 6 days, which requires caution in generalizing the results; the lack of verification of the Red Call function for emergencies; and the fact that the evaluation was primarily quantitative. For RT data, each nurse could contribute multiple events across multiple days. The primary analysis addressed this by aggregating events to a per-nurse median before testing (n=15 per condition), and a linear mixed effects model was fitted as a sensitivity check; both analyses yielded congruent results. The per-category RT analyses, however, retained the event-level unit of analysis because each nurse contributed too few events per category for per-nurse aggregation within a category to be informative. Per-category *P* values were corrected for multiplicity across the 6 request categories using Bonferroni adjustment (adjusted α=.0083); 2 categories (Care Help and Information Sharing) remained significant after correction, while 2 further categories (Consultation and Confirmation to Nurse) showed nominal reductions that did not survive correction and should be regarded as hypothesis-generating. Additionally, the alternating-day, between-subjects design is susceptible to temporal confounding from factors, such as staffing variation, patient census, and workload differences between study days. Although day-level clustering was examined in a prespecified sensitivity analysis (Table S2 in Multimedia Appendix 1) and did not alter the substantive conclusion, day-level confounders cannot be fully excluded with the present design and require confirmation in a larger study with a greater number of study days.

Conclusions

This study demonstrated that a simple signal communication app using BLE Mesh network technology significantly reduces RTs among nurses and markedly improves the core teamwork elements of Situation Monitoring and Mutual Support. This indicates that the app has immediate and practical value in improving the inefficiency of communication in nursing practice and enhancing the quality of team-based medical care.

Abstract

Background: Ineffective clinical handover has the potential to compromise patient safety and quality of care. Standardizing the handover process is a widely adopted improvement strategy intended to reduce failures of information transfer. By enabling real-time access to patient information, electronic medical records (EMRs) could address communication issues inherent to nursing handover.

Objective: This case study sought to compare the quality of nursing handover occurring at EMR-enabled sites with that occurring at paper-based sites, within a single Australian public health service.

Methods: A comparative case study design was used, using quantitative data collected from observational audits of 60 handovers and posthandover surveys conducted in EMR-enabled and paper-based ward environments. Handover quality was measured through compliance with the organization's Clinical Handover Standard and staff-reported perceptions, enabling comparison between cohorts.

Results: Compared with paper-based wards, EMR-enabled wards demonstrated more consistent communication of clinical alerts and risks and fewer interruptions, whereas paper-based wards showed higher rates of bedside handover and patient engagement.

Conclusions: EMR implementation alone does not ensure high-quality nursing handover. EMR interface design and functionality may act as a barrier to bedside handover and patient engagement, and contribute to continued reliance on paper-based artifacts. Targeted EMR design and nursing informatics-led optimization are required to better support nursing handover as a complex and cognitively challenging communication process.

KEYWORDS

nursing handover; electronic medical record; electronic health record; health information systems; patient engagement

Introduction

Overview

Nurses play a vital role in determining the clinical outcomes of their patients, particularly in relation to ensuring patient safety and continuity of care [1]. Extensive research demonstrates that deficiencies in clinical communication processes represent a significant risk to patient safety [2] and are a common source of sentinel events [3]. When communication is incomplete, unclear, or inaccurate, patient safety may be compromised [1]. Clinical handover is a critical and complex health care communication process, serving as the primary mechanism for transferring responsibility and accountability between shifts [4]. Effective and high-quality nursing handover is a core patient safety mechanism, facilitating the timely, accurate, and efficient exchange of clinical information [5]. Consistent with the National Safety and Quality Health Service (NSQHS) Standards, effective handover requires information to be clear, comprehensive, and precise to support safe, appropriate, and continuous care [6].

XSL•FO
RenderX

Conversely, inadequate or poorly executed clinical handovers can adversely affect patient outcomes [5]. Ineffective communication during handover has been associated with inaccurate clinical assessments [7], delayed diagnoses [6], inappropriate treatments, and medication errors [5]. The impacts of these failures range from minor disruptions to care to severe and potentially catastrophic outcomes. As health care systems increasingly adopt electronic medical records (EMRs) to support clinical communication, understanding how these systems influence the quality and safety of nursing handover is essential.

Background

Efforts to structure and standardize nursing handover processes are often recognized as key improvement strategies for improving the quality and safety of clinical communication [8]. Standardized communication protocols and structured handover tools such as ISOBAR (Identification Situation Observations Background Assessment/Action Recommendation) [9] are "intended to prevent failures of information transfer" [10] by ensuring that information shared is relevant, concise, and focused [5]. Handover mnemonics like ISOBAR reduce the cognitive workload associated with performing handover [11,12] and were designed to overcome differences in communication styles, a factor contributing to communication errors [13]. By streamlining the handover process, these tools also enhance situational awareness within team-based environments, supporting the development of a shared mental model of a patient's clinical status [13,14]. Standardizing handover processes is therefore a frequent recommendation aimed at improving handover quality and patient outcomes.

In Australia, NSQHS Standards provide a quality assurance mechanism and "a nationally consistent statement about the standard of care consumers can expect from their health service organizations" [15]. NSQHS Standard 6, "Communicating for Safety includes the criterion for communication at clinical handover," encompassing structured clinical handover, defining minimum information content of handover, key principles of clinical handover, and engaging patients and caregivers in clinical handover processes [15].

Increasingly, bedside handover has been adopted as standard practice in Australian hospitals [1] and is promoted as a strategy to enhance patient engagement, transparency, and patient-centered care [16]. Best practice bedside handover requires nurses to communicate accurate, comprehensive, and contemporaneous clinical information in real time [5], often in the presence of the patient, their families, and caregivers. While this model of handover offers important benefits [1,16], it also increases the complexity of information exchange [17], requiring nurses to synthesize and communicate large volumes of clinical data efficiently [18] while maintaining patient engagement [16] and situational awareness [11,13]. These demands place heightened emphasis on the availability, accuracy, and usability of clinical information at the point of care, and on the systems through which that information is accessed and communicated during handover.

In this context, EMRs have been introduced internationally as a means of supporting complex clinical communication processes, including nursing handover. EMRs are clinical information systems that facilitate real-time access to patient data and provide structured system-level processes intended to support patient safety, quality improvement, and compliance with expected standards of practice [19,20]. Key patient safety mechanisms include electronic prescribing and medication administration, the use of alerts, checklists, and predictive tools and embedded evidence-based practices, supporting decision making at the point of care [19,21]. Beyond strengthening compliance, EMRs also enable continuous quality improvement by generating routinely collected data that can be used to monitor performance, identify variations in practice, and inform iterative improvement cycles [19].

With real-time access to up-to-date patient information, EMRs have been proposed as a means to address the communication challenges inherent to clinical nursing handover [9]. EMRs have the potential to support nursing handover through the use of structured EMR-based handover tools, thus aligning with the intent of NSQHS Standard 6, by supporting timely, accurate, and standardized communication of critical patient information [5].

The introduction of an EMR in itself does not guarantee improvements in clinical communication or patient safety. The literature remains equivocal regarding the extent to which EMRs improve efficiencies in health care, with some studies noting potential adverse effects on nursing handover, including increased work and decreased efficiencies [22,23]. Poorly planned or ineffective implementations of an EMR may disrupt established nursing workflows and may fail to provide the required cognitive support nurses require during handover [22,24]. Information fragmentation within EMRs and the need to navigate multiple screens or data sources may further increase nurses' cognitive workload during handover, introducing new risks for both patients and clinicians [25,26]. Understanding both the intended benefits and unintended consequences of EMR adoption is essential to assessing their value in practice [27,28].

While EMRs provide the technological infrastructure to support structured and standardized handover, the effective translation of EMR functionality into safe and high-quality nursing practice is underpinned by nursing informatics capability. Nursing informatics describes the knowledge and skills required by registered nurses to integrate nursing science with information and computer sciences to manage, communicate, and apply clinical data, information, and knowledge in practice [29].

The presence of digital technology alone is insufficient to improve clinical outcomes. Contemporary nursing practice requires nurses to navigate an increasingly complex digital environment, meaningfully engage with digital systems, adapt workflows, and effectively use information within the realities of clinical practice [30,31], including during time-critical activities such as nursing handover. Nursing Informatics, therefore, provides an interpretive and operational lens through which the impact of EMR-facilitated handover can be understood. Within this context, nurses play a critical role in shaping documentation practices, information use, and workflow integration [32,33] in ways that either support or undermine the

XSL•FO
RenderX

safety and quality objectives of a structured, best-practice nursing handover, occurring at the patient's bedside.

While handover standardization alone has the potential to improve the effectiveness and efficiency of nursing handover and contribute to safer patient care [15], high-quality research linking the implementation of EMR-facilitated structured nursing handover to impacts on patient-related outcomes is still lacking. A knowledge gap therefore exists, as does an opportunity for further exploration of EMR-mediated solutions that may serve to support, standardize, and therefore enhance nursing handover.

Despite the widespread implementation of EMRs and increasing adoption of bedside handover, there remains limited empirical evidence examining how EMR-facilitated structured nursing handover translates into practice, particularly when compared with handover occurring in non-EMR environments within the same health service. Understanding how differences in information systems, workflow integration, and nursing informatics capability influence the quality of handover is essential to determining whether EMRs achieve their intended safety and quality objectives.

This gap is particularly salient for health services implementing EMRs in a staged or hybrid manner, where variations in digital maturity create a natural opportunity to examine the impact of EMR-enabled handover in context. It is within this organizational and digital landscape that the present case study was situated.

Context

Eastern Health is a large public health service situated in Victoria, Australia, serving a wide catchment across Melbourne's east. The organization spans 6 local government areas, covering 2816 square kilometers and comprising 21 health service locations. Eastern Health's 3 largest acute hospital sites are Box Hill Hospital, Maroondah Hospital, and Angliss Hospital.

A full EMR was implemented at Box Hill Hospital in October 2017. At Angliss Hospital, Electronic Medication Prescribing and Administration was implemented in November 2016; however, inpatient clinical documentation has remained predominantly paper-based. At the time of the study (conducted March to May 2023), implementation of the full EMR across inpatient wards at Maroondah Hospital (including Electronic Medication Prescribing and Administration) and completion of the full EMR deployment at Angliss were planned for late 2025 and early 2026, respectively. As a result, Eastern Health operated within a hybrid digital environment with varying levels of maturity across sites.

The introduction of full EMR at Box Hill Hospital fundamentally altered the interface through which nurses accessed, synthesized, and communicated clinical information during handover. In contrast, nurses at Maroondah and Angliss continued to rely primarily on paper-based documentation supported by other limited digital systems. These contrasting documentation environments, operating within the same organization, provided a structured basis for systematic comparison of EMR-enabled and predominantly paper-based nursing handover within a shared organizational context.

The sampling frame comprised nursing handovers conducted on all acute general medical and acute general surgical wards across Box Hill, Maroondah, and Angliss Hospitals. Each site has a 24-hour emergency department and intensive care unit, providing comparable patient cohorts within their respective acute medical and acute surgical wards. The selection of these was intended to promote homogeneity between the EMR-enabled and non-EMR sites, thereby minimizing the impact of variability in patient acuity on nursing expertise and handover practices. A total of 12 wards were identified as suitable for inclusion in the study. The target population comprised clinical nursing staff responsible for conducting routine shift-to-shift handovers.

Study Purpose

The purpose of this case study was to examine and compare the quality of nursing handover conducted in fully EMR-enabled wards at Box Hill Hospital with handover occurring in predominantly paper-based documentation environments at Maroondah and Angliss Hospitals. Handover quality was examined within routine clinical practice and assessed using two complementary measures: (1) the degree of compliance with the organization's Clinical Handover Standard, and (2) clinical nursing staff's self-reported perceptions of handover quality.

This purpose aligns with the study's focus on understanding how differences in documentation environments and information access may shape the conduct and perceived quality of bedside nursing handover within a shared organizational context.

Aims

The primary aim of this study was to compare the quality of nursing handover in fully EMR-enabled wards and predominantly paper-based wards within acute inpatient settings.

Specifically, the study sought to compare nursing handover practices in fully EMR-enabled wards with those occurring in predominantly paper-based environments, by examining whether EMR presence was associated with:

- Higher-quality nursing handover, as measured by compliance with the organization's Clinical Handover Standard (Multimedia Appendix 1).
- Differences in duration of nursing handover.
- Differences in the level of patient engagement in the handover process.
- Differences in staff-reported perceptions of handover quality.

Methods

Design

To address the study purpose and aims, nursing handover practices were examined across EMR-enabled and predominantly paper-based wards within the same health service. This study used a comparative quantitative case-study design using 2 complementary quantitative data sources.

XSL•FO
RenderX

Case study research is "a distinctive form of empirical enquiry" [34] that investigates a contemporary phenomenon within its real-life context [35]. This approach is well-suited to health care settings, where complex clinical processes can be examined using observational methods alongside other data sources, allowing meaningful characteristics of real-world practice to be retained [34], while generating opportunities for more comprehensive explanations [36].

As described within the context section of this case study, the staged implementation of the EMR across Eastern Health provided a naturalistic opportunity to apply a comparative case study design, enabling examination of nursing handover practices in wards supported by a fully implemented EMR alongside those operating in predominantly paper-based environments. Comparative evaluations of health information systems remain relatively uncommon, with much of the existing literature relying on descriptive or correlational approaches [27]. As such, this design offered the potential to generate contextually grounded insights relevant to both local system optimization and the broader evidence base on formative evaluations of digital health systems.

This case study used 2 quantitative data collection instruments. First, structured observational audits of routine shift-to-shift nursing handover were conducted to assess handover quality based on observed compliance with key principles of Eastern Health's Clinical Handover Standard. Second, posthandover surveys were administered to capture clinical nursing staff's perceptions of the quality of handover received, with responses quantified using Likert-scales, responses to closed yes/no questions, and counts of affirmative responses. For both data sources, comparisons were undertaken between handover occurring in the EMR-enabled wards and those in predominantly paper-based wards. This multi-source quantitative approach enabled direct observation of the phenomenon being studied alongside quantified staff perceptions of handover quality [34].

Consistent with guidance on health information system evaluation, the use of multiple data sources allowed complementary insights to be integrated, supporting a more comprehensive understanding of nursing handover within differing documentation environments [27]. EMR-supported handover was examined from a nursing informatics perspective, focusing on nurses' use of available documentation systems and the clinical information exchanged during routine handover practice.

The data collected and analyzed in this case study form part of a broader program of research examining nursing handover processes within EMR-enabled clinical environments. Subsequent analyses will explore nurses' interaction with, and use of, EMR functionality during handover in greater depth.

Participants

The study was conducted across acute general medical and acute general surgical inpatient wards within 3 hospital sites of a single public health service in Victoria, Australia. Participants in the observational audits and posthandover surveys were nurses conducting routine shift-to-shift nursing handovers on the 12 selected wards during the data collection period. The distribution of wards by site, documentation environment, and the number of handovers audited is presented in Table 1.

Table . Selected wards by site and number of handovers audited.

Site	Medical wards	Surgical wards	Medical record status	Total number of wards	Number of handovers audited
Box Hill	3	3	Full EMR[a]	6	30
Maroondah	2	2	Paper-based	4	20
Angliss	1	1	Paper-based	2	10
Total	6	6	—[b]	12	60

[a]EMR: electronic medical record.

[b]Not applicable.

For this comparative case study, the case was defined as the selected wards within the 3 hospitals of a single public health service. The unit of analysis was the individual shift-to-shift nursing handover. Data were collected between March and May 2023, across morning and afternoon shifts, encompassing both paper-based and EMR-enabled documentation environments.

Sampling

A convenience sampling approach was used, whereby nurses giving handover on the selected wards during scheduled data collection periods were invited to participate. To promote variation in observed practice, handovers were sampled sequentially across different days, shifts, and times within each ward to capture variation in routine practice. Five handovers per ward were targeted to ensure adequate representation of routine handover practices within each clinical context, while remaining feasible given the resource-intensive nature of direct observational auditing across multiple sites. Five nursing handovers were sampled per ward, resulting in a total of 60 observed handovers across the 12 wards.

Inclusion and Exclusion Criteria

Eligibility for participation was defined to ensure consistency across wards and sites.

Inclusion Criteria

Participants were eligible if they were registered nurses with current nursing registration, used by Eastern Health, and scheduled to participate in shift-to-shift nursing handover during the data collection period. All participants were required to provide informed consent.

XSL•FO
RenderX

Exclusion Criteria

Undergraduate nurses, assistants in nursing, agency nurses, and staff who declined to participate or did not consent to the collection of basic demographic information were excluded from the study.

Ethical Considerations

Ethics approval was obtained from Eastern Health's Human Research Ethics Committee, HREC number LR22-042-84698. Reciprocal ethics approval was obtained from La Trobe University. Written informed consent was obtained from all nurse participants involved in the observational audits and posthandover surveys, including nurses giving and receiving handovers. Patients whose handovers were observed were provided with written information about the observational audit in advance. Patients were informed that no personal identifiers or health information would be collected or recorded as part of the audit. Verbal consent to proceed with handover observation was obtained from patients immediately prior to handover commencement. Participants received no financial or other compensation for their participation.

Data Collection

Overview

A total of 60 observational audits and corresponding posthandover surveys were conducted between March and May 2023. Observational audits occurred during the morning-to-afternoon (AM to PM) shift-to-shift nursing handover. All observational audits were undertaken by a single auditor to ensure consistency. Both the observational audit tool and the posthandover survey were completed using paper-based instruments at the point of data collection. Immediately following each observed handover, the nurse receiving the handover completed a posthandover survey. All paper-based data were subsequently entered into REDCap by the same auditor later on the day of collection, following completion of data collection activities for that day.

Each nurse was observed delivering handover once; however, nurses may have received handover and completed the posthandover survey on more than one occasion, consistent with the sampling approach and routine practice, resulting in up to 120 participants.

For each participating ward, 5 observational audits and posthandover surveys were completed over a period of 1 to 2 days. The observational audits comprised 30 handovers in fully EMR-enabled wards and 30 handovers conducted and observed in predominantly paper-based documentation environments. As this study represented an observational comparative case study and an exploratory examination of nursing handover practices, formal sample size or power calculations were not undertaken.

Observational Audit

The observational audit was designed to quantify the quality of nursing handover by measuring compliance with the organization's Clinical Handover Standard (Multimedia Appendix 1). This Standard addresses 11 key principles underpinning best practice clinical handover and is aligned with the NSQHS Standard 6: Communicating for Safety. These principles are summarized in Table 2.

XSL•FO
RenderX

Table . Principles for best practice handover. Extracted from the Eastern Health Clinical Handover Standard, November 2022, available in Multimedia Appendix 1.

Number	Principle
1	Are undertaken using a consistent and structured process, "ISOBAR,"[a] which includes a minimum dataset.
2	Recognize that clinical handover requires effective communication between clinicians, including an opportunity to clarify information.
3	Maintain the patient's right to confidentiality and privacy; sharing of information is based upon the relevance and impact to care and outcomes
4	Promote inclusion of patients and, where appropriate, their caregivers, while acknowledging that sensitivity is required where other patients or visitors may overhear patient information.
5	Consider the need to engage interpreters if patients have communication difficulties, such as cultural and linguistic diverse backgrounds or hearing impairments.
6	Occur prior to, or at the time when clinician/s transfer care and accountability, and acknowledge the transfer of accountability for some or all of the patient's care.
7	Ensure adequate preparation prior to undertaking a clinical handover, making certain that the process is efficient and that all relevant information is transferred.
8	The clinician providing direct care leads the clinical handover, and where possible, handover occurs as face-to-face communication.
9	Respect the importance of handover, with minimal interruptions or distractions.
10	Within mental health settings, a team handover occurs prior to individual handover to ensure all staff are aware of the current milieu and risk issues present within the unit.
11	Documentation of the handover is recorded within the progress notes, or equivalent, in accordance with the Clinical Documentation Standard.

[a]ISOBAR: Identification Situation Observations Background Assessment/Action Recommendation.

Health service organizations are required to implement governance frameworks, systems, and processes that support effective clinical communication during handover. Locally contextualized clinical handover standards provide a mechanism through which NSQHS requirements are operationalized at the organizational level, thereby supporting patient safety and quality of care [15].

Audit Tool Development

The observational audit tool was developed to assess whether handovers complied with established principles of effective clinical communication. Tool development occurred in partnership with Eastern Health's Communicating for Safety Clinical Risk Governance Committee (CFS CRGC) to ensure content validity and alignment with established clinical governance standards. Audit questions were aligned with those used in previous organization-wide Clinical Nursing and Midwifery Handover Audits, enabling comparison with existing organizational data and reinforcing alignment with established quality and safety processes.

In determining the final audit tool, several decisions were made:

- Two principles of the Clinical Handover Standard (Principles 10 and 11) were considered outside of the scope of this study and were therefore excluded.
- The location of handover was identified as a key variable of interest in the context of a newly introduced digital interface. Specified within the Standard is that "where possible, clinical handover will occur face to face and in the patient's presence (bedside handover)." This element was therefore included as a distinct principle for auditing.
- Handover efficiency was measured through handover duration and whether handover commenced and concluded on time, with all required staff present.
- Respect for the handover process was quantified by recording the number of interruptions occurring during each handover episode.

Ten principles were therefore included in the final audit framework. A total of 28 audit questions were used to assess compliance with these principles. Each question required a yes or no response, with the exception of interruptions and handover duration, which were recorded as counts and time (minutes), respectively. The full list of audit questions and their alignment with each principle is presented in Table 3.

XSL•FO
RenderX

Table . Observational audit questions in relation to each principle.

Principle	Questions	Response	Interpretation and data analysis
Handover occurs at the bedside	• Did handover occur at the bedside?	Y/N	% compliance with the principle per ward/cohort/overall.
Handover follows ISOBAR[a]	• Identify: Was the person/team involved in the handover introduced to the patient? • Identify: Was a 3-point ID check completed? • Situation: Was the current clinical situation of the patient (ie, stable, improving, deteriorating, and discharge plan) discussed? • Observation: Were recent clinical observations discussed? • Background: Was the relevant patient background/history, evaluation, and management to date shared? • Assessment: Were relevant clinical assessments, any concerns from assessments, or outstanding assessments/actions discussed? • Assessment: Were clinical risks (ie, falls, pressure injuries, delirium, malnutrition, behavior of concern [BOC]) discussed? • Assessment: Were clinical alerts (ie, safety concerns such as aggression/harms to others, infection control) discussed? • Request/recommendation: Were actions required and recommendations for ongoing care discussed, including responsibility for actions and agreed transfer of responsibility?	Y/N	% compliance for each question and % compliance with the principle per ward/cohort/overall.
Communication is effective	• Did the nurse leading the handover provide an opportunity to ask questions? • Did the nurse receiving the handover ask any questions to clarify the information received? • Did the nurse receiving the handover ask any questions to seek information that was not offered?	Y/N	Principle deemed met if any 1 question answered in the affirmative and % compliance with the principle per ward/cohort/overall.
Patient's right to confidentiality is maintained	• Was all the information provided at the bedside clinically relevant, avoiding information pertaining to sensitive social or clinical conditions?	Y/N	—[b]

XSL•FO
RenderX

Principle	Questions	Response	Interpretation and data analysis
Inclusion of the patient, family, or caregiver is promoted	• Was the patient greeted during the handover process? • Was the handover process explained to the patient? • Was the patient and caregiver/family member present included in the handover? • Was the patient given an opportunity to ask questions or discuss goals or raise concerns?	Y/N	% compliance for each question and % compliance with the principle per ward/cohort/overall.
Interpreters are used where needed	• Is the patient's first language or native language a language other than English? • Is there a language barrier present that would prevent the patient from being included in the handover? • Was an interpreter used during handover? • Was the future planning or booking, or did an interpreter discuss?	Y/N	% compliance with the principle per ward/cohort/overall. Logic used: If N recorded for Q1 or Q2=N/A If Y recorded for Q1 & Q2 (interpreter deemed needed) AND Y recorded for either Q3 OR Q4 (interpreter is used or planned)=Y/N.
Transfer of care and accountability is acknowledged	• Was there an acknowledgment of a transfer of care or accountability? *SELECT ALL THAT APPLY: • Discussion of actions required and responsibility for actions occurred • Review of treatment and care plan, clinical risks, management, and recommendations occurred • Review of information and clarification sought by the recipient • Acknowledgment and agreement from the recipient of the plan of care	Y/N. Principle deemed met if any 1 question answered in the affirmative	% compliance with the principle per ward/cohort/overall.
The direct care clinician leads handover and, where possible, delivered face to face	• Did the clinician providing direct care lead the handover? • Was the handover delivered face to face?	Y/N	% compliance for each question and % compliance with the principle per ward/cohort/overall.
Respect for process – minimized interruptions and distractions	Was the handover interrupted?	Number of interruptions recorded	Number of interruptions recorded per ward/cohort/overall.
Handover is efficient	Time taken to deliver the handover	Duration of handover in minutes (rounded)	Duration of handover per ward/cohort/overall.
Handover is efficient	Handover started and finished on time, with all required staff present?	Y/N	% compliance for the question.

[a]ISOBAR: Identification Situation Observations Background Assessment/Action Recommendation.

[b]Not applicable.

Posthandover Survey

The posthandover survey was designed to complement the objective data captured in the observational audits by capturing the immediate assessment of handover quality from the perspective of the handover recipient. Survey items were developed to quantify staff perceptions of satisfaction, quality, efficacy, and efficiency associated with each handover episode. This approach is consistent with the literature, which emphasizes the importance of accurate and comprehensive communication during clinical handover to support patient safety [6].

The survey was developed collaboratively with the organization's CFS CRGC to ensure alignment with clinical

XSL•FO
RenderX

handover principles and organizational standards, and comprised 11 items: 5 Likert-scale questions, 5 closed-ended (yes/no) questions, and 1 free text response. Likert-scale items were scored on a 5-point scale, with a composite score (out of 25) calculated for questions assessing satisfaction, quality, and perceived efficacy. Closed-ended items were analyzed using frequency counts and percentages. Free-text responses were reviewed descriptively; however, due to limited volume and specificity, they were not subjected to formal qualitative analysis. The full list of posthandover survey questions, response formats, and corresponding analytical approaches is provided in Table 4.

While formal psychometric analyses (eg, internal consistency) were not feasible due to the exploratory nature of the study, sample size, methodological triangulation with the observational audits supported interpretive validity.

XSL•FO
RenderX

Table . Posthandover survey questions.

Question	Construct	Response	Interpretation and data analysis
Are you satisfied with the handover you just received?	Satisfaction	Likert scale 1 - 5: 1=very dissatisfied 2=dissatisfied 3=neither satisfied nor dissatisfied 4=satisfied 5=very satisfied	Score (out of 5) for each question per ward/cohort/overall Composite score (out of 25) for questions 1 - 5 per ward/cohort/overall
Rate the overall quality of the handover received	Quality	Likert scale 1 - 5: 1=very poor 2=poor 3=average 4=good 5=excellent	Composite score (out of 25) for questions 1 - 5 per ward/cohort/overall
Did the handover follow the ISOBAR format?	Quality	Likert scale 1 - 5: 1=strongly disagree 2=disagree 3=neither agree nor disagree 4=agree 5=strongly agree	Composite score (out of 25) for questions 1 - 5 per ward/cohort/overall
Rate how accurate you believe the handover was?	Efficacy	Likert scale 1 - 5: 1=very poor 2=poor 3=average 4=good 5=excellent	Composite score (out of 25) for questions 1 - 5 per ward/cohort/overall
Rate how comprehensive you believe the handover was?	Efficacy	Likert scale 1 - 5: 1=very poor 2=poor 3=average 4=good 5=excellent	Composite score (out of 25) for questions 1 - 5 per ward/cohort/overall
Was the required content effectively communicated?	Efficacy	Y/N	% occurrence (count of yes) per ward/cohort/overall
Were you given the opportunity to clarify information?	Efficacy	Y/N	% occurrence (count of yes) per ward/cohort/overall
Was there any specific information you felt was missing?	Efficacy	Y/N	% occurrence (count of no) per ward/cohort/overall
If Y to Q8: In a few short words, briefly state what information you believe was missing	Efficacy	Free text	To be themed where possible
Was the duration of handover appropriate?	Efficiency	Y/ N - too short N - too long	% occurrence (count of yes) per ward/cohort/overall
Was the inclusion of the patient, family, or caregiver promoted?	Quality	Y/N	% occurrence (count of yes) per ward/cohort/overall

It should be noted that staff perceptions of patient engagement were higher than what was observed in audits, suggesting possible overestimation due to social desirability bias or limited understanding of effective patient inclusion during handover. This discrepancy highlights the importance of combining objective and self-reported measures when evaluating handover quality.

RenderX

Data Analysis

Overview

Data were extracted from REDCap into Microsoft Excel by the research team and deidentified prior to analysis. All data handling and analysis complied with institutional governance, ethical, and privacy requirements.

Observational Audits

For each audit question, the frequency of affirmative responses was calculated. Compliance with each handover principle was determined by aggregating question-level responses and summarized at the ward level, by cohort (EMR-enabled vs paper-based), and for the overall sample. Descriptive statistics, including mean and median values where appropriate, were generated to enable comparison between cohorts. The detailed analytic approach, itemized by audit question, is presented in Table 3.

Nonparametric tests (Kruskal-Wallis rank-sum test) were used for intergroup comparisons due to nonnormal distribution of data. Handover duration and frequency of interruptions were analyzed descriptively.

Posthandover Surveys

Posthandover survey data were analyzed descriptively. Likert-scale responses were summarized using mean and median values at the ward level, by cohort, and overall. For closed-ended (yes/no) questions, frequencies and percentages of affirmative responses were calculated across the same groupings.

A composite score was derived from the 5 Likert-scale items assessing satisfaction, quality, and perceived efficacy to provide an overall measure of staff perceptions of handover quality. Comparative analysis was undertaken to examine alignment between staff-reported perceptions and observed handover quality as measured through compliance with the Clinical Handover Standard.

The posthandover survey also included a single free-text question inviting respondents to identify any information they believed was missing from handover. Responses were limited and lacked sufficient depth for qualitative analysis and were therefore not subjected to formal qualitative analysis or reported in this paper.

Given the exploratory nature of the study and the relatively small sample size, formal effect size estimation was not undertaken, and results were interpreted primarily descriptively.

Validity and Reliability

Overview

The observational audit and posthandover survey instruments were developed in collaboration with the organization's CFS CRGC, supporting content validity and ensuring alignment with established clinical governance standards. Audit items were mapped directly to the organization's Clinical Handover Standard and aligned with the NSQHS Standard 6: Communicating for Safety, ensuring construct relevance and consistency with best-practice frameworks.

To enhance the validity of the findings, objective measures of handover quality derived from observational audit compliance with the Clinical Handover Standard were compared with self-reported staff perceptions of the handover quality captured through the posthandover survey, providing methodological triangulation. Use of a single trained auditor and standardized data collection procedures further supported reliability and methodological rigor.

Observational Audits

Design of the observational audits was purposefully aligned with previous organization-wide Clinical Nursing and Midwifery Handover Audits. This alignment supported consistency in measurement and enabled comparison with existing audit data, strengthening confidence in the reliability of the observational audit approach.

Posthandover Survey

As the posthandover survey captured individual staff perceptions, inherent limitations relating to subjectivity and response bias are acknowledged. While the survey instrument had not been previously administered within the organization, its development was informed by established handover constructs and aligned with the observational audit framework, supporting interpretive validity.

Results

Observational Audits

Overview

Observational audit data were first analyzed to compare overall compliance with the Clinical Handover Standard between paper-based and EMR-enabled wards. Compliance with individual principles of the Standard was then examined to identify areas of variation between the 2 cohorts.

Overall Compliance With the Clinical Handover Standard

Overview

Overall compliance with the Clinical Handover Standard was assessed across 10 key principles. Eight of these principles were evaluated as either met or not met. Table 5 presents percentage compliance for each of these 8 principles, along with overall compliance by cohort, expressed using mean and median values. This composite measure, derived from compliance across the audited principles, indicated broadly comparable overall handover quality between EMR-enabled and paper-based wards.

XSL•FO
RenderX

Table . Overall compliance with the standard.

Principle	Paper-based[a]		EMR[b]-enabled[c]	
	Mean	Median	Mean	Median
Handover occurs at the bedside (%)	83	80	63	60
Handover follows ISOBAR[d] (%)	80	78	83	78
Communication is effective (%)	100	100	100	100
Patient's right to confidentiality is maintained (%)	100	100	100	100

[c]Respect for process: 7 interruptions.

[d]ISOBAR: Identification Situation Observations Background Assessment/Action Recommendation

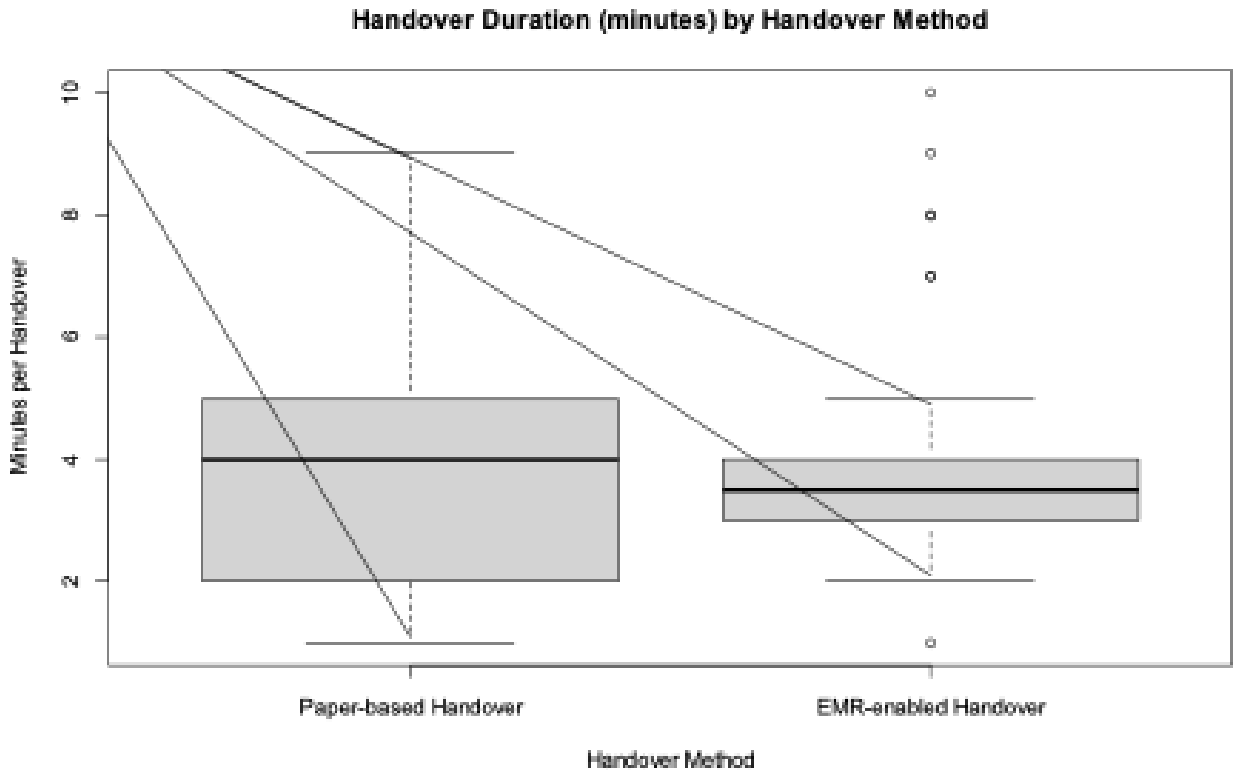
[e]Not applicable. The principle, "Interpreters are employed as needed,"demonstrated insufficient data for comparative analysis, with only 2 instances of interpreter need identified across the sample. This has been reported descriptively and excluded from composite compliance to avoid disproportionate influence on results.

Paper-based wards demonstrated slightly higher mean overall compliance with the Clinical Handover Standard (90%) than EMR-enabled wards (84%), although median compliance was equivalent across cohorts. This pattern suggests broadly comparable aggregate performance, with observed differences driven by variation across specific handover principles, rather than consistent divergence across all domains.

The 2 remaining principles, "Respect for Process" and "Handover is Efficient," were assessed using alternative metrics, quantified by the number of interruptions that occurred, and the duration of handover, respectively.

Interruptions During Handover

Across the 60 handovers observed, a total of 8 interruptions were recorded. Seven interruptions occurred in 2 paper-based wards, while only one interruption was observed in an EMR-enabled ward.



Handover Duration

Median handover duration was slightly longer in paper-based wards (4 min) compared with EMR-enabled wards (3.5 min). Initial analysis was considered using ANOVA; however, the data failed tests of normality (Shapiro–Wilk test for normality). Consequently, nonparametric methods, including the Kruskal–Wallis rank-sum test, were used. This analysis indicated no statistically significant differences between the paper-based and EMR-enabled wards, likely influenced by the small sample size.

As illustrated in Figure 1, the median handover duration was slightly longer for paper-based handover (4 min) compared with EMR-enabled handover (3.5 min), suggesting a marginally quicker handover in EMR settings. However, the IQR was wider for paper-based handovers (2.75 vs 1), indicating greater variability within the middle 50% of values, suggesting more consistent handover duration in EMR-enabled settings.

XSL•FO
RenderX

Figure 1. Handover duration by handover method.

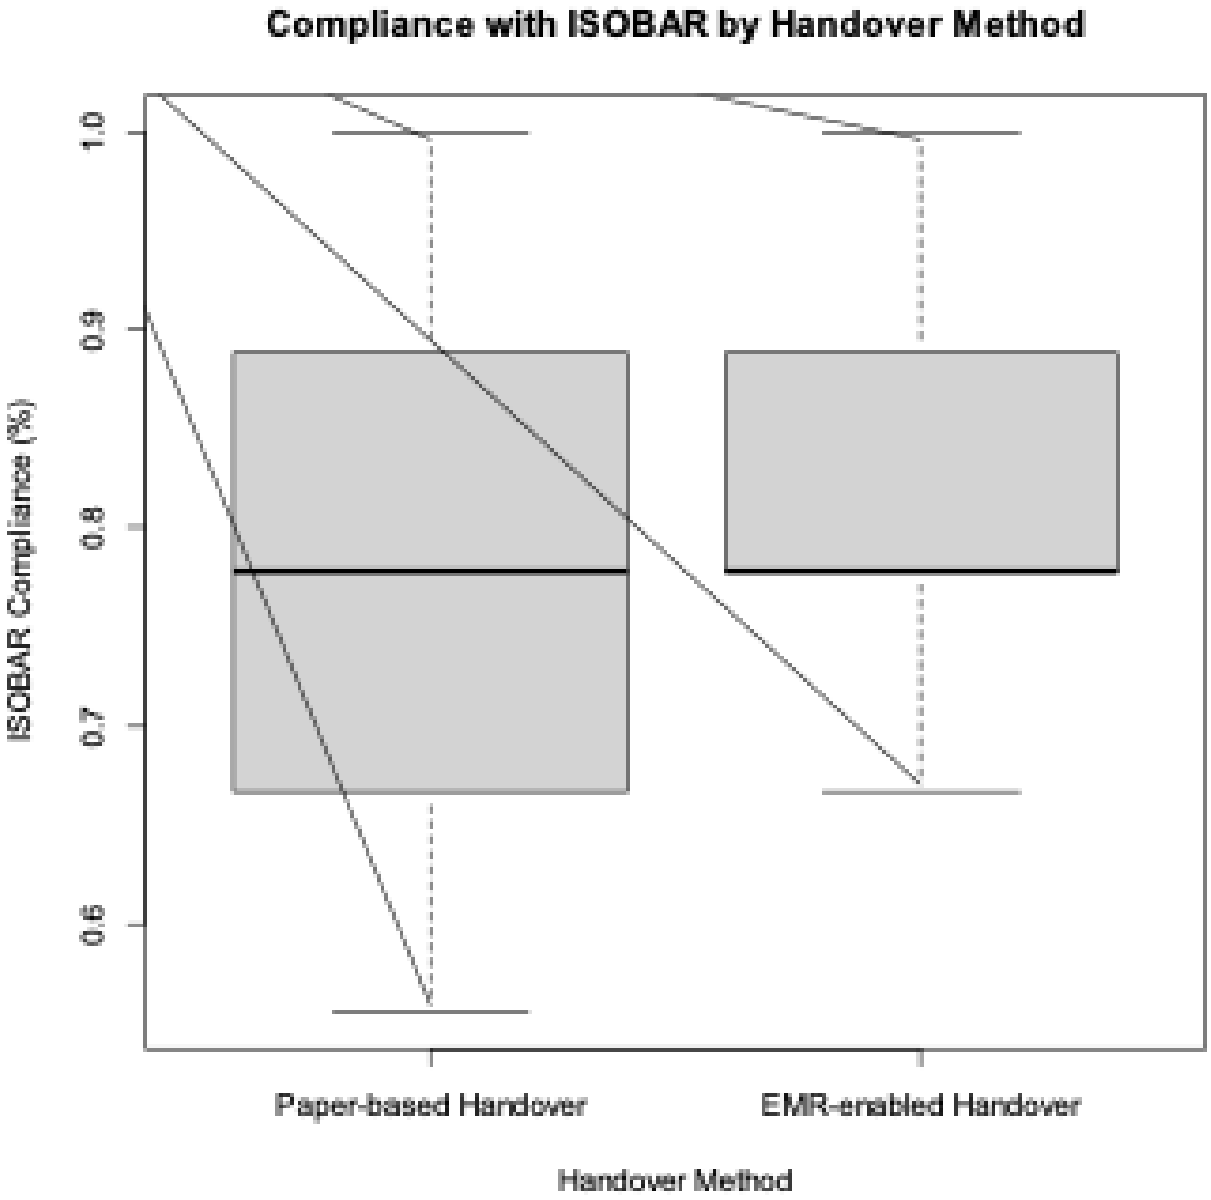
Compliance Against Individual Principles of the Standard

Overview

Four principles demonstrated 100% compliance across all 12 wards:

- Communication is effective,
- Patient's right to confidentiality is maintained,
- Transfer of care and accountability occur,
- Direct care clinician leads handover.

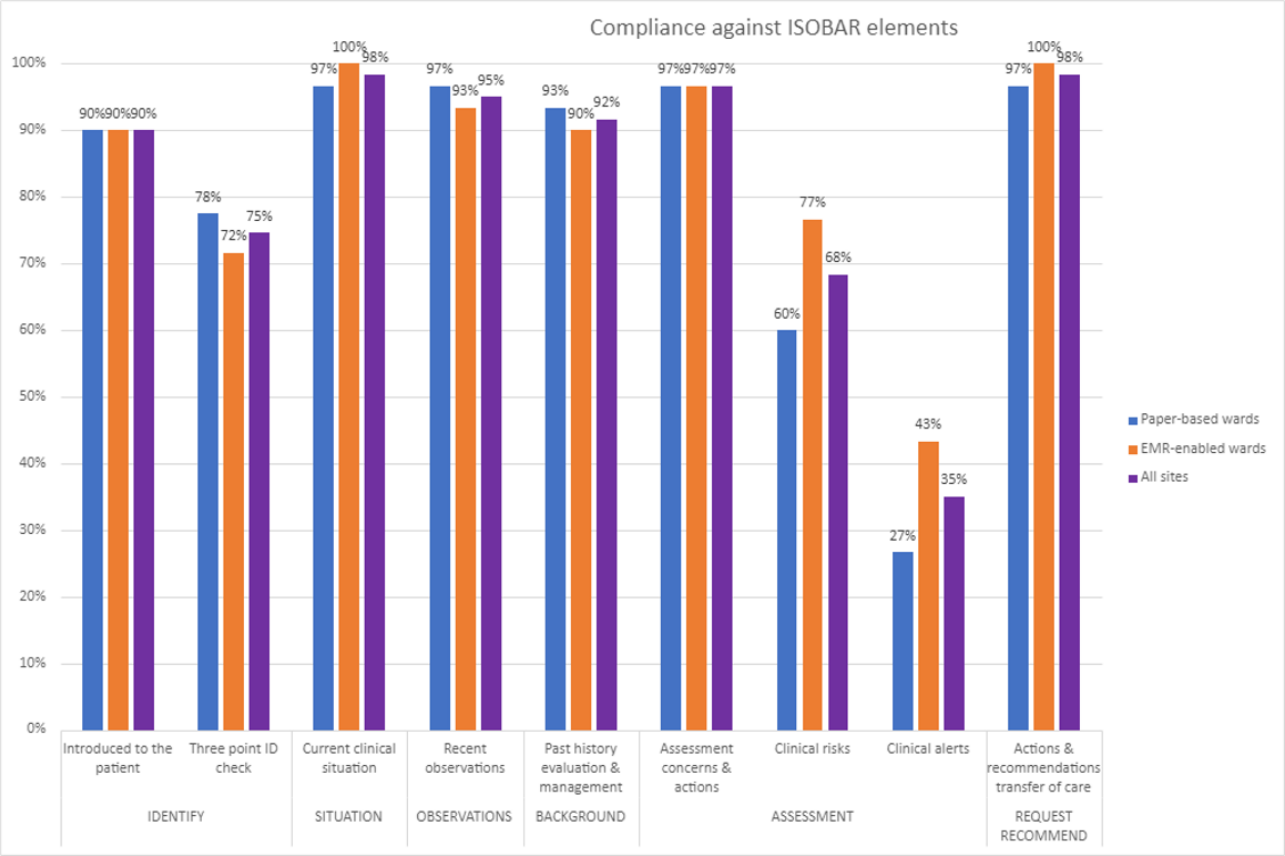
Analysis of the remaining principles revealed several areas of divergence between cohorts, as outlined below.



Compliance With ISOBAR

Compliance with all 9 ISOBAR elements was reviewed for both cohorts. Median compliance scores were equivalent between cohorts (0.778); however, EMR-enabled wards demonstrated a slightly higher mean compliance score (0.833) compared with paper-based wards (0.804). Paper-based wards exhibited greater variability, reflected by a wider IQR (0.194 vs 0.111). Both cohorts achieved the maximum possible compliance score of 1.0. These findings are illustrated in Figure 2.

Further examination of individual ISOBAR elements identified differences in the discussion of clinical risks and clinical alerts (Figure 3).



XSL•FO
RenderX

Figure 2. Compliance with ISOBAR by handover method. EMR: electronic medical record; ISOBAR: Identification, Situation, Observations, Background, Assessment/Action, Recommendation.

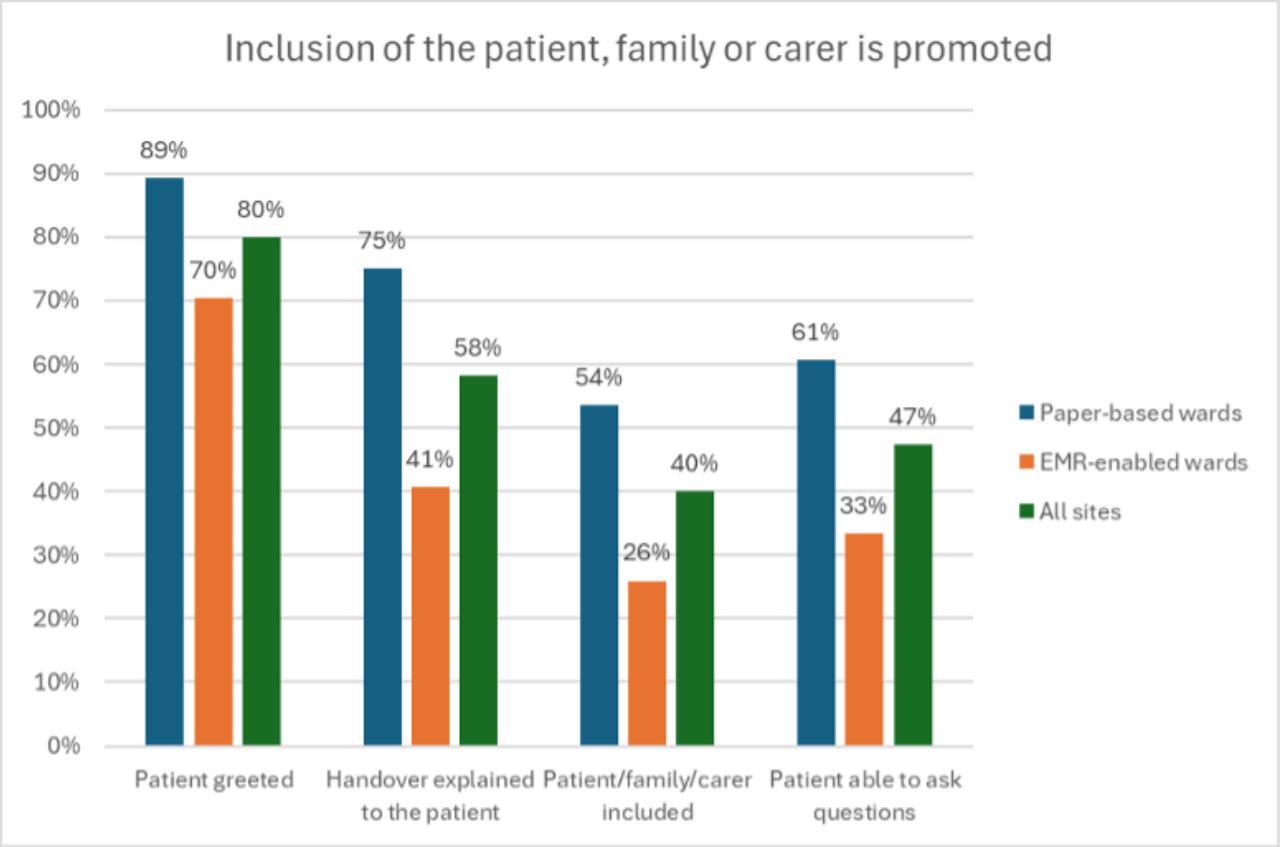
XSL•FO
RenderX

Figure 3. Compliance against ISOBAR elements. EMR: electronic medical record; ISOBAR: Identification, Situation, Observations, Background, Assessment/Action, Recommendation.

Clinical Risks and Clinical Alerts Were Discussed

Handover of clinical risks and clinical alerts occurred more frequently in EMR-enabled wards. Clinical risks were discussed in 77% of EMR-enabled handovers compared with 60% in paper-based wards, while clinical alerts were discussed in 43% of EMR-enabled handovers compared with only 27% in the paper-based wards.

Bedside Handover



Handover occurred at the bedside more frequently in paper-based wards, with a mean compliance of 83%, compared with 63% in EMR-enabled wards.

Inclusion of the Patient, Family, or Caregiver

Promotion of patient, family, or caregiver inclusion occurred more frequently in paper-based wards. Compliance with all 4 patient inclusion indicators was observed in 70% of handovers in paper-based wards, compared with 43% in the EMR-enabled wards (Figure 4).

XSL•FO
RenderX

Figure 4. Inclusion of the patient, family, or caregiver is promoted. EMR: electronic medical record.

Comparison With Organization-Wide Handover Audits

Observational audit findings were compared with results from Eastern Health's Clinical Handover Nursing and Midwifery Audits conducted in 2022‐2023. Areas identified for improvement in the organization-wide audits aligned closely with findings in this case study, particularly in relation to bedside handover and patient and caregiver involvement.

Notably, overall performance relating to patient and caregiver inclusion was lower in this case study than in the organization-wide audits, suggesting potential variability in practice interpretation and reinforcing the need for further exploration of what constitutes effective patient inclusion and engagement in handover. Overall, these observational findings suggest that EMR availability was associated with variation in how handover was enacted across specific domains, rather than a uniform improvement or decline in overall handover quality.

Posthandover Surveys

Overview

Analysis of the posthandover survey data commenced with the calculation of a composite score derived from the 5 Likert-scale questions assessing staff satisfaction, perceived handover quality, adherence to ISOBAR, accuracy, and comprehensiveness of handover. A maximum composite score of 25 was possible. Results for individual items and composite scores by cohort are presented in Tables 6 and 7.

XSL•FO
RenderX

Table . Posthandover survey results (Likert scale questions). Overall score across all survey questions was 92% (median 97%) for paper-based and 91% (median 97%) for electronic medical record (EMR)-enabled handover.

Question	Paper-based mean (score)	Paper-based mean (%)	Paper-based median (score)	Paper-based median (%)	EMR-enabled mean (score)	EMR-enabled mean (%)	EMR-enabled median (score)	EMR-enabled median (%)
1. Are you satisfied with the handover you just received?	4.73	95	5	100	4.67	93	5	100
2. Rate the overall quality of the handover received	4.60	92	5	100	4.43	89	5	100
3. Did the handover follow the ISOBAR[a] format?	4.40	88	5	100	4.53	91	5	100
4. Rate how accurate you believe the handover was?	4.80	96	5	100	4.70	94	5	100
5. Rate how comprehensive you believe the handover was?	4.60	92	5	100	4.47	89	5	100
Composite score (Q1-Q5)	23.1	93	23	92	22.8	91	23	92

[a]ISOBAR: Identification Situation Observations Background Assessment/Action Recommendation.

Table . Posthandover survey results (Closed questions). Overall score across all survey questions was 92% (median 97%) for paper-based and 91% (median 97%) for electronic medical record (EMR)-enabled handover.

Closed questions (Y/N)	Paper-based mean (%)	Paper-based median (%)	EMR-enabled mean (%)	EMR-enabled median (%)
6. Was the required content effectively communicated?	100	100	100	100
7. Were you given the opportunity to clarify information?	100	100	97	100
8. Was there any specific information you felt was missing? (count of no)	93	100	90	100
10. Was the duration of handover appropriate?	93	100	100	100
11. Was the inclusion of the patient, family, or caregiver promoted?	70	70	70	70

Composite scores demonstrated minimal difference between cohorts, indicating similar levels of staff satisfaction and perceived handover quality. Across 10 of the 11 survey questions, responses were overwhelmingly positive, with no mean scores falling below 88% in either cohort.

Staff perception of the promotion of patient, family, or caregiver inclusion was the only survey item demonstrating a notable reduction in perceived performance.

Staff Perception - Promotion of Patient Inclusion

While observed patient engagement during the observational audits was limited, staff-reported perceptions indicated higher levels of patient involvement during handover. Promotion of patient inclusion was recorded as equivalent across cohorts, with both paper-based and EMR-enabled wards reporting 70% affirmative responses to this survey item.

XSL•FO
RenderX

Discussion

Principal Findings

This case study examined the impact of EMR implementation on both the process and perceived quality of nursing handover. Particular attention was given to how digital information systems shape nurses' access to, synthesis of, and communication about patient information. In this study, handover quality was operationalized using 2 complementary process-level measures: observed compliance with the organization's Clinical Handover Standard, and nurses' self-reported perceptions of handover quality following shift-to-shift handover exchange. Together, these measures provide insight into how EMR-mediated workflows influence handover behaviors, rather than downstream patient outcomes. Overall, EMR implementation did not uniformly improve handover quality; rather, its effects were heterogeneous across process domains, partially supporting the study objectives.

Quantitatively, overall compliance with the Clinical Handover Standard did not differ meaningfully between EMR-enabled and paper-based wards, nor did overall staff perceptions of handover quality. However, analysis of individual observational indicators revealed variation across specific domains. These included bedside location of handover, promotion of patient engagement, communication of clinical risks and alerts, handover duration, and frequency of interruptions. These findings suggest that while aggregate measures of handover quality appeared comparable, EMR implementation influenced *how* handover was enacted across specific components of the process.

Observational Audits

EMR-Facilitated Handover Creates a Barrier to Performing Bedside Handover

Observational audit data demonstrated a lower frequency of bedside handover in EMR-enabled wards compared with paper-based wards.

Bedside handover encourages direct and real-time engagement with the patient [1]. Active patient participation in the process can provide immediate information on the patient's condition [1]. Moreover, exchanging clinical information in the patient's presence can assist in identifying patient concerns, promoting continuity, quality of care, and improved patient satisfaction [1]. Implementing bedside handover is therefore key to promoting and supporting patient engagement and participation in care.

In this study, the presence of the EMR appeared to act as a barrier to nurses performing bedside handover. This finding points to challenges associated with EMR implementation that may, in turn, reduce the level of patient engagement during handover. The following factors may help explain this finding.

Limitations of the Physical Environment

In the EMR-enabled wards in this case study, nurses access the EMR on mobile workstations via computers mounted onto purpose-built trolleys, commonly referred to as Workstations on Wheels (WOWs). While ergonomic and adequately mobile, these WOWs are still relatively large. Often observed during the observational audit was one nurse from the AM shift giving handover to 2 nurses on the PM shift. Frequently, both nurses receiving handover would each be interacting with their own WOW. At times, the nurse giving handover would also be accessing the EMR on their own WOW, though this appeared to occur less frequently, with the nurse giving handover most commonly referring to their own printed handover sheet, inclusive of hand-written notes.

Despite the EMR-enabled wards being located in a relatively new and modern facility with spacious patient rooms, the available physical space at the bedside remained insufficient for 3 nurses and 2 WOWs. The devices are bulky and difficult to maneuver. As a result, staff appeared reluctant to take the WOWs fully into patient rooms and were frequently observed remaining in or just outside the doorway. The lead researcher was also made aware that in some patient rooms within the EMR-enabled cohort, Wi-Fi connectivity was reduced, resulting in poor or limited EMR functionality at the bedside.

Social Barriers to Using Technology at the Bedside

In addition to these identified physical limitations, a more nuanced barrier is a social one, where the presence of the EMR at the patient's bedside may be perceived as incongruous with a therapeutic environment. A positive and workable nurse-patient relationship develops when trust is established and maintained through an open exchange of information, supporting the delivery of interpersonal care [37,38]. In inpatient hospital settings, the nurse-patient relationship develops at the patient's bedside. Use of active listening techniques during nurse-patient interactions, such as making and maintaining appropriate eye contact, facing the patient, and minimizing distractions [37,38], further contributes to this therapeutic connection. Introducing digital technology into the therapeutic bedside space may be perceived by nurses as intrusive. It may disrupt active listening practices and interfere with the development of the therapeutic relationship. The patient may therefore perceive that the information being shared is not valued.

Duffy et al [38] similarly note that EMR documentation at the point of care can distract nurses' attention from the patient. This may reduce communication quality, appropriate eye contact, and overall meaningful interaction [38]. Misto [39] explored the impact of electronic documentation in the patient's presence on the nurse-patient relationship and noted that nursing staff perceptions of the EMR's influence on the therapeutic relationship were mixed [39]. Positive impacts included enhanced access to data at the patient's bedside and the ability to document contemporaneously and more efficiently, resulting in more time to spend with the patient [39]. Negative impacts centered on the recurring premise that using the EMR at the bedside is a distraction, resulting in both 'missed opportunities to connect with patients,' and an increased likelihood that subtle, nonverbal cues could be missed [39]. This was attributed to nurses being preoccupied with interacting with the EMR rather than being fully attentive to the patient [39]. Nurses in that study

XSL•FO
RenderX

also reported that patients felt less valued when this occurred [39].

Gaudet [40] also explored the changes in nurse-patient interactions associated with the introduction of EMR documentation at the bedside, noting that this may create "an automatic, machine-like, task centered bedside environment" [40].

It is therefore possible that nurses feel that the insertion of a large and bulky, potentially distracting piece of digital technology into the space at the patient's bedside may negatively impact the therapeutic relationship, serving only to make handover more impersonal rather than enhance it.

Cognitive Barriers to Performing EMR-Facilitated Handover at the Bedside

A recent review article exploring the impact of an EMR implementation on nursing handover determined that existing EMR interfaces are not currently meeting the needs of nurses during handover [22]. Navigating the EMR has been shown to impact cognitive workload due to the range of tasks required of users [26]. Combined with the way information is presented in the EMR, this results in fragmented or siloed data that must be skimmed through, sorted, and deciphered [18,24,25]. In this study, nurses were frequently required to navigate multiple EMR screens to locate alerts, risks, and clinical updates, reflecting well-recognized information fragmentation within EMR systems [25]. In this context, fragmentation shifts cognitive effort away from clinical reasoning and toward system navigation [25,41].

Handover is already a cognitively challenging task, requiring the nurse to be able to swiftly analyze and synthesize patient data across multiple information sources [24,42,43] and engage in complex knowledge-sharing processes [18]. The expectation that this demanding task also occurs at the bedside, involves the patient, and is mediated through an EMR that is often difficult to navigate, may further increase this burden. This raises an important question: Does this combination unintentionally work against the goal of improving handover quality and patient engagement? Is the presence of the patient themselves now an additional barrier to achieving the desired level of handover quality? Gaudet [40] explores this conundrum where 'the complexity of the patients, the computerized prioritisations of tasks and the interruptions, limited the nurses' ability to nurture and become familiar with their patients, thus creating "an environment that does not put the patients' concerns at the center of care" [40].

From an informatics perspective, EMR-mediated handover requires nurses to simultaneously navigate, prioritize, and synthesize information. At the same time, they must maintain effective interpersonal communication with both colleagues and patients. Together, these demands increase cognitive workload during an already complex task. Given that a fully optimized EMR solution for nursing has not yet been realized [22], nurses may be reluctant to bring EMR-facilitated handover to the bedside. Doing so may be perceived as increasing complexity and potentially compromising handover quality.

Patient Engagement Was Better Promoted in Paper-Based Environments

Where a reduced frequency of bedside handover was observed in the EMR-enabled cohort, so too were lower levels of patient engagement and decreased promotion of patient, family, and caregiver inclusion in handover. Although the compliance gap for initially greeting the patient was smaller between the cohorts, meaningful patient inclusion cannot occur when handover takes place away from the bedside. This was demonstrated by the widening performance gaps for the remaining patient engagement indicators, "Including the Patient in Handover" and "Providing the Patient an Opportunity to Ask Questions."

Reduced frequency of bedside handover in the EMR-enabled wards was therefore identified as a stand-alone barrier to promoting patient engagement as measured by observational indicators of inclusion and the opportunity to ask questions.

Other Known Barriers to Bedside Handover and Patient Engagement

Despite the known benefits of bedside handover in improving patient engagement and supporting patient-centered care, studies continue to elucidate reluctance from nurses to perform handover at the bedside. Independent of EMR introduction, commonly cited barriers to bedside handover include concerns about patient privacy and confidentiality [44-46]. Nurses also report worries about being asked difficult questions or appearing unprofessional in front of patients [44,45]. Additional concerns relate to perceived prolongation of handover [47,48] and disruption to communication flow [46,47].

A pre-existing resistance to bedside handover for these myriad reasons must therefore be considered as a contributing factor to the gap in bedside handover implementation across both cohorts in this study. Where an existing baseline gap in practice may already be evident, the introduction of the EMR, and all the additional potential barriers it brings, has possibly further compounded this issue in the EMR-enabled wards, making bedside handover even less achievable.

Handover of Critical Information Occurred More Readily in EMR-Enabled Wards

In the hospital environment, EMRs are accessed by clinicians throughout the course of a patient's treatment, replacing bulky paper-based medical records. In this case-study context, an EMR was introduced and mobile WOWs provided, providing up-to-date clinical information at the point of care and during handover. An EMR facilitates real-time sharing of patient data and has the potential to improve efficiency and care coordination [49]. The results of the observational audit support this, with improved handover of critical information such as clinical alerts and clinical risks evident in the EMR-enabled wards compared with the paper-based cohort.

This also aligns with marginally better performance observed for overall ISOBAR compliance in the EMR-enabled wards, where more consistent practice in using the mnemonic may have contributed to the improved handover of risks and alerts.

RenderX

Reliance on Other Tools to Support Handover

In paper-based environments in this case study, nurses predominantly rely on printed handover sheets generated by bed management software known as Patient Flow Manager (PFM). PFM is not linked to the organization's EMR and clinical information stored within it, and it does not form part of the medical record.

To populate these handover sheets, clinical information is transcribed from the scanned patient history or EMR and manually entered into PFM. Nursing staff add and update clinical information in PFM throughout their shift, including the removal of any outdated information. It is not routinely used by medical or allied health staff in this way. Unfortunately, a reliance on duplication and manual data entry processes has the potential to result in transcription errors, decreasing the accuracy of the information contained on these handover sheets. Conversely, the EMR is considered the source of truth for clinical patient information, inclusive of clinical alerts and clinical risks, which have been configured to provide a visual alert to clinicians.

In the EMR-enabled wards, nurses also use PFM and are provided with PFM-generated printouts at the commencement of their shifts. In these wards, however, the EMR is always accessible during handover and is frequently used to check information, most notably by the handover recipients. This is consistent with recent studies, which predominantly described EMR use during handover as verifying or double-checking information [24,25,41] and keeping up to date with the latest developments [18].

In paper-based environments, nurses rely heavily on printed handover sheets. The information on these sheets may be outdated, incomplete, or inaccurate. Where critical changes in the patient's condition occur, it is imperative that nurses are immediately aware of changes to any clinical alerts and clinical risks. This will ensure that the most appropriate care, interventions, and safety precautions can be implemented to promote patient and staff safety.

Persistent reliance on PFM-generated paper handover sheets was observed in both cohorts, including the EMR-enabled wards. In this study, this pattern signaled a socio-technical misalignment between the EMR design and nursing handover workflows. Despite the EMR being the authoritative source of clinical information, nurses continued to depend on nonintegrated artifacts to support their cognitive load, information sequencing, and real-time note-taking during handover. This behavior suggests that existing EMR interfaces did not adequately support nurses' information needs during handover, reinforcing findings that poor task–technology fit drives workarounds and partial adoption of digital systems [22].

Handover Was More Efficient in the EMR-Enabled Wards

Observational audit data demonstrated reduced median handover duration in EMR-enabled wards compared with paper-based wards. Performance was also more consistent in the EMR-enabled environments, with more variability of duration noted in the paper-based wards.

Across a number of studies, accessing and navigating the EMR has been described as time-consuming [24,41], cumbersome [41], arduous [24], and not necessarily able to provide pertinent information quickly [43].

Despite these potentially negative connotations, studies reporting specific impacts of EMR implementation on handover duration offered mixed results. Hertzum and Simonsen [50] sought to understand the impact of a trial EMR implementation, finding that there was no significant difference in handover duration postintervention [50]. Correspondingly, Alghenami's [51] 2012 study exploring the role of EMRs in structuring handover communications found that nurses did not identify the EMR as a factor that would impact handover duration [51]. There is growing evidence, however, that use of specific EMR-structured handover tools or EMR-generated printouts can assist in making handover quicker and more efficient [52-54]. It is important to note, nonetheless, that positive outcomes are highly contingent on whether these tools are adequately aligned with the nature of the clinical work [55] and offer sufficient functionality to support the task [56]. Conversely, where an EMR interface does not adequately suit the task at hand, it fails the end user, which may result in incomplete adoption of the new technology and a continued reliance on paper-based tools [22]. Ultimately, when a gap in functionality or design is not readily addressed, or poor user experience persists, this has the potential to lead to user frustration and even boycott [56].

At Eastern Health, in the EMR-enabled wards, nurses were observed navigating various parts of the EMR during handover, yet they did not use any specific EMR-structured handover tools or EMR-generated printouts. Further to this, nurses across both cohorts were almost always observed consulting or making handwritten notes on paper handover sheets printed from PFM. Nurses in the EMR-enabled cohort demonstrated willingness to adopt EMR use during handover. However, the continued reliance on PFM-generated printouts suggests a gap in EMR design or functionality. While the PFM-generated printouts clearly provide support to nurses during handover, they remain problematic as they do not draw clinical information directly from the EMR. Ideally, an EMR-generated printout would replace those generated via PFM and thus provide the most up-to-date clinical information. Ultimately, these printouts must be purposefully designed by and for nurses in order that they fully support the task being performed.

Handover Occurring in EMR-Enabled Wards Experienced Fewer Interruptions

The paper-based cohort experienced more interruptions during handover, noting this may well be an anomaly given the very small sample size. Current research on the impact of interruptions during EMR use appears limited to those that occur via the EMR itself, such as automated alerts, reminders, and other clinical decision support mechanisms [57-59], or broader workflow interruptions associated with EMR implementations in general [60-62]. This case study sought to measure external interruptions caused by patients, phones, alarms, or other staff in the ward environment. The reason for fewer interruptions occurring in the EMR-enabled cohort is, therefore, entirely speculative.

XSL•FO
RenderX

A very well-researched field that could offer some useful comparisons is the frequency and impact of interruptions on medication administration workflows, which have the potential to result in medication errors. As a known high-risk activity, efforts to prevent and reduce interruptions that may lead to errors during medication rounds have also been thoroughly explored. Frequently used strategies to reduce and manage the risk of interruptions include the use of standardized checklists and protocols such as the 5 rights of medication administration, quiet zones for medication preparation, diversion strategies, and visual alerts such as wearable sashes and vests asking that others "Do Not Disturb" and "Do Not Interrupt" [63-65]. Nurses are therefore highly aware of this increased risk to patient safety, noting also that these types of interruptions are significant contributing factors to increasing mental workloads in hospital work environments [66]. One possible explanation is that engagement with the EMR may provide a visible cue to other staff that nurses are occupied with handover, potentially reducing external interruptions in a manner similar to visual "Do No Disturb" signals used during medication administration.

These findings should therefore be interpreted as indicative process trends rather than definitive performance improvements, and further investigation with larger samples or longitudinal designs may clarify their significance.

Staff Perception of Patient Engagement

Observational audit findings relating to patient engagement during nursing handover did not correlate with staff's self-reported perceptions of their own efforts to promote patient participation.

While bedside handover alone is insufficient to ensure meaningful patient engagement in the process [45], it remains a fundamental prerequisite in order for patient participation to occur. In this study, observational audits identified a compliance gap with bedside handover across both cohorts, with this gap more significant in the EMR-enabled wards. On this basis, lower observed rates of bedside handover in the EMR-enabled cohort would be expected to correspond with similarly reduced rates of self-reported promotion of patient engagement during handover. And yet the staff survey found that this was occurring in equal proportions across both cohorts, around 70% of the time.

The large mixed methodology study of Street et al [45] examining patient participation in handover may assist in explaining this, observing that whilst nurses do perceive the value in patient participation, 'the best way to effectively help patients be more involved in bedside nursing handover is poorly understood' [45]. The findings of this case study support this notion, suggesting that nurses, who may not understand how to effectively engage patients, may have limited insight into whether their handover practices genuinely facilitate patient engagement and participation.

This discrepancy may reflect an overestimation of patient engagement in staff self-reported data, potentially influenced by social desirability bias, whereby participants provide responses and report practices that are perceived as more acceptable [67]. In this instance, the self-reported practice aligned better with organizational expectations and the requirements of the Clinical Handover Standard, despite the decreased incidence of bedside handover necessary to facilitate the desired engagement.

Collectively, these findings highlight the value of using multiple measurement approaches when evaluating handover quality, as reliance on self-report alone may overestimate adherence to patient engagement principles.

Staff Satisfaction With Handover Quality

Despite the reduced occurrence of bedside handover, potential data fragmentation, workflow changes, and reliance on workarounds (including paper-based and nonintegrated artifacts) in EMR-enabled wards, staff satisfaction with overall handover quality remained high across both cohorts. Clinicians may report satisfaction with systems they have learned to cope with, even when those systems impose additional cognitive or workflow burdens [56]. These findings likely reflect nurses' ability to adapt to existing system constraints rather than optimal alignment between EMR design and nursing handover workflows.

Taken together, these findings suggest that staff satisfaction alone is an insufficient indicator of EMR effectiveness, reinforcing the need to examine how digital systems shape cognitive workload, workflow integration, and communication practices during nursing handover.

The contrast between consistently high staff satisfaction and observed variability in handover behaviors suggests adaptation and normalization of system constraints, reinforcing the importance of examining both objective and perceptual measures when evaluating digital clinical systems. Integrating observational and perceptual data strengthened interpretive validity and enabled identification of important differences between enacted and perceived practice that would not have been apparent using a single measurement approach.

Limitations

Several limitations should be considered when interpreting the findings of this study.

First, the relatively small sample size of 60 handovers limited the ability to detect statistically significant differences across all measures, particularly given the complexity and variability inherent in clinical handover practices. While sampling 5 handovers per ward enabled exposure to routine practice within each setting, the number of observations per cohort was insufficient to support more granular analyses or make more robust comparisons. As a result, findings should be interpreted as indicative of patterns of use and areas of variation rather than definitive estimates of practice prevalence. In addition, this study focused on process-level indicators of nursing handover quality, including observed compliance with the organization's Clinical Handover Standard and nurses' self-reported perceptions of handover quality. These measures provide important insights into how handover is conducted in different environments but do not directly assess patient outcomes or safety events. As such, findings should be interpreted as reflecting differences in handover processes only. Furthermore,

XSL•FO
RenderX

as an exploratory case study conducted within a single health service, the findings have limited generalizability beyond similar organizational and hybrid EMR contexts. However, the design provides rich, practice-based insight into how nursing handover is shaped within real-world digital environments.

Second, the use of a single auditor introduces the potential for investigator bias. To mitigate this risk, the observational audit tool was designed to minimize subjectivity, with items structured wherever possible to limit reliance on auditor interpretation. Consistent use of a single trained auditor also supported standardization of data collection across sites.

Third, a degree of Hawthorne effect may have occurred, as participants were aware that they were being observed. This is particularly relevant for highly visible elements of the Clinical Handover Standard, such as conducting handover at the bedside and performing patient identification checks. While this may have influenced overall adherence to the Clinical Handover Standard, it is unlikely to have affected the comparative analysis between the 2 cohorts, as any observation effect would have been equally probable in both groups.

Finally, the study focused exclusively on shift-to-shift nursing handover within inpatient wards and did not include handovers occurring in other settings such as interdepartmental transfers and other transitions of care. Future research should consider observing and evaluating handovers across a broader range of clinical contexts, with particular attention to how EMRs are configured and used to facilitate and support nursing handover under varying workflow, environmental, and cognitive demands.

Conclusions

This case study demonstrates that EMR implementation has the potential to produce both beneficial and unintended effects on the quality of shift-to-shift nursing handovers. While EMR-enabled wards showed positive impacts in accessing and communicating up-to-date clinical information, particularly in relation to clinical alerts and risks, these benefits did not translate uniformly across all dimensions of handover quality.

Findings indicate that a pre-existing reluctance to perform bedside handover may be exacerbated in EMR-enabled environments, with negative implications for patient inclusion and engagement. Limitations related to the physical environment, EMR interface and design, social factors, and cognitive factors appear to impede nurses' ability to consistently promote patient participation during handover. These findings suggest that nurses may not have a clear or comprehensive understanding of the actions necessary to actively promote patient engagement, nor how to effectively assess these efforts, a challenge that appears more pronounced in digitally mediated handover contexts. This suggests a gap in informatics-enabled support for nursing practice, particularly in translating digital handover processes into patient-centered behaviors.

Positive impacts of EMR implementation included improved efficiency and reduced interruptions during handover, indicating a degree of user acceptance and adaptation. However, continued reliance on paper-based PFM-generated handover forms highlights persistent gaps in EMR functionality or design, and the need for workarounds to support cognitive and workflow demands during handover. While this study did not examine patient or safety outcomes directly, it provides important process-level evidence to inform the optimization of nursing handover within digitally enabled environments.

Collectively, these findings indicate that the presence of an EMR alone is insufficient to ensure high-quality nursing handover. Rather, the impact of EMR implementation on handover quality is mediated by nursing informatics capability and the degree to which digital systems are designed and aligned with nurses' cognitive processes and clinical workflows. Where EMR interfaces fragment information or fail to provide integrated, task-specific handover views, nurses compensate through workarounds that may limit the potential benefits of digital systems. Optimizing nursing handover in digitally enabled environments requires EMR designs that explicitly support handover as a complex, cognitively demanding, and safety-critical nursing activity, rather than assuming that quality improvements will occur through digitization alone.

Future Research

Future research should examine in greater depth how nurses interact with EMR systems during handover, including patterns of use, information navigation, and reliance on workarounds. Detailed analysis of user interaction with the EMR would assist in determining the degree to which the current technology suits the task being undertaken and which current digital tools are suited to the cognitive and workflow demands of nursing handover.

Qualitative exploration of nurses' perceived barriers and facilitators to EMR use during handover would further inform understanding of how EMR interface design, functionality, workflow integration, and device availability may influence handover practices. Such insights could support the identification of design flaws that contribute to the ongoing reliance on paper-based handover forms and other nonintegrated artifacts in EMR-enabled environments.

Future studies may benefit from the evaluation of discrete components of EMR implementation, including device footprint, software interface design, workflow integration, and overall user experience, to better understand each element's relative impact on the quality and effectiveness of nursing handover.

Comparative analyses across wards or sites with differing levels of digital maturity, including electronic prescribing and medication administration, may offer further clarification as to how specific EMR functionalities influence nursing handover processes and outcomes.

Acknowledgments

We are grateful for the clinical governance expertise, support, and input from members of the Communicating for Safety Clinical Risk Governance Committee in the development of the audit tools used in this case study.

Abstract

Background: Older adults with diabetes are vulnerable, facing multimorbidity and challenges in reaching glycemic targets. When insulin therapy is required, limited knowledge of geriatric therapeutic goals often leads to regimens that increase the risk of hypoglycemia. Simplified approaches such as once-daily basal insulin are recommended, yet titration protocols and unclear regimens remain barriers in home care nursing. Digital decision support systems (DDSSs) such as GlucoTab address this gap by offering evidence-based titration guidance integrated into nursing workflows. DDSSs also strengthen nurse autonomy, which leads to improved care processes and better outcomes in home care settings.

Objective: This study assessed the effects of a nurse-guided intervention including a DDSS for diabetes management in older adults with type 2 diabetes receiving home care nursing.

Methods: The prospective quasi-experimental feasibility and implementation study was conducted using GlucoTab for diabetes management as part of a multicomponent intervention at 2 home care nursing sites. Nine adults with type 2 diabetes receiving insulin therapy were enrolled (n=5 women; mean age 77, SD 10 years; mean BMI 27.7, SD 4.7 kg/m^2; mean baseline hemoglobin A_{1c} 59.5, SD 12.8 mmol/mol). After receiving training, nurses implemented the DDSS, which integrates evidence-based diabetes management recommendations for home care and nursing workflows. Diabetes-related hospital admissions and glycemic outcomes were assessed before, during, and after implementation of the DDSS intervention.

Results: Before implementation, 5 diabetes-related emergency admissions led to 4 hospitalizations, compared with none during implementation and 4 after implementation, mostly due to hyperglycemia. The median hospital stay was 9 (IQR 8-15) days (before and after implementation). Diabetes management shifted from predominantly premixed insulin therapy at baseline to basal insulin with or without bolus insulin during implementation. Diabetes-related home care visits decreased from 1.81 to 1.01 per day (before vs during implementation), and general practitioner contacts for insulin adjustments declined (19 before implementation vs 16 after implementation). Mean morning blood glucose decreased from 212 (SD 72) mg/dL to 162 (SD 42) mg/dL, and the proportion of measurements within the target range (70 - 180 mg/dL) increased from 39.0% to 70.8% before vs during implementation. No incidence of hypoglycemia requiring third-party help was observed during implementation. Adherence of nurses to DDSS recommendations exceeded 94%.

Conclusions: This study suggests that integrating a DDSS in a multicomponent intervention into home care nursing yielded longitudinal changes in diabetes outcomes. Emergency visits and hospitalizations were lower during implementation, no severe hypoglycemia was observed, glycemic control improved throughout the observation period, and therapy was simplified in routine care. Nursing visits decreased, suggesting potential improvements in care processes and resource use. High adherence and acceptance by nurses indicate feasibility and usability in home care practice. These findings align with evidence from hospitalized patients and telehealth studies, suggesting the potential for clinical, safety, and efficiency benefits.

Introduction

Background

Worldwide, approximately 422 million people live with diabetes, most residing in low- and middle-income countries. The prevalence of diabetes has been steadily increasing across all income levels over recent decades [1]. The most common form is type 2 diabetes, accounting for more than 90% of all cases worldwide, with prevalence rising further in geriatric populations due to increasing life expectancy. In this context, Europe represents one of the regions with the highest diabetes prevalence worldwide, with a substantial and growing proportion of older adults affected, placing increasing pressure on health care systems and home-based care services [2].

Complexity of Diabetes Management

Diabetes is a chronic, metabolic disorder characterized by elevated blood glucose levels and can be accompanied by a range of complications, including microvascular and macrovascular damage, as well as a multitude of common comorbidities (eg, hypertension, obesity, cardiovascular disease, and chronic kidney disease) [3]. Older adults in particular face an increased risk of adverse health outcomes due to comorbidities and often fail to achieve age-appropriate glycemic goals [4]. Clinical evidence confirms that effective blood glucose management can reduce diabetes-related complications [5]. The American Diabetes Association recommends simplified treatment regimens for older adults, emphasizing hypoglycemia prevention as a critical factor of individualized glycemic targets. With the aging population, more older adults will live with diabetes, and age-related declines in self-management skills and memory may further complicate care. Basal insulin regimens, often administered via prefilled pens once daily, are especially suitable for older adults due to their ease of use and low hypoglycemia risk. Despite the availability of modern antihyperglycemic agents, some individuals with type 2 diabetes will ultimately require and benefit from insulin therapy due to decreasing endogenous insulin secretion. Evidence from hospitalized patients with type 2 diabetes has shown that a basal-bolus regimen is clearly superior to premixed insulin, resulting in fewer hypoglycemic events at comparable mean blood glucose levels [5,6].

Empowering Nurses in Diabetes Care

Older adults with diabetes in home care nursing frequently do not receive optimal diabetes management due to lack of information, support, and professional cohesion [7,8]. Effective chronic diabetes management demands an interdisciplinary approach in which nurses represent a leading, empowered player. Enhancing nurses' clinical autonomy, confidence, access to up-to-date information, and appropriate training is essential to enable this role [9]. Nurse-led care models have consistently shown to improve the outcomes of people with chronic diseases such as diabetes. Outcomes also include improved quality of care, better chronic disease management, and reduced health care use in primary care settings [10]. Evidence indicates that nurses often spend a great deal of time engaging with individuals, enabling more comprehensive assessment and support [11]. Systematic reviews further show that nurse-led interventions are associated with higher patient satisfaction; reductions in hospitalizations; and, in some cases, even lower mortality [12]. Additionally, care delivered by well-trained nurses can be as effective or even superior to that provided by primary care physicians [13].

Digital Decision Support Systems

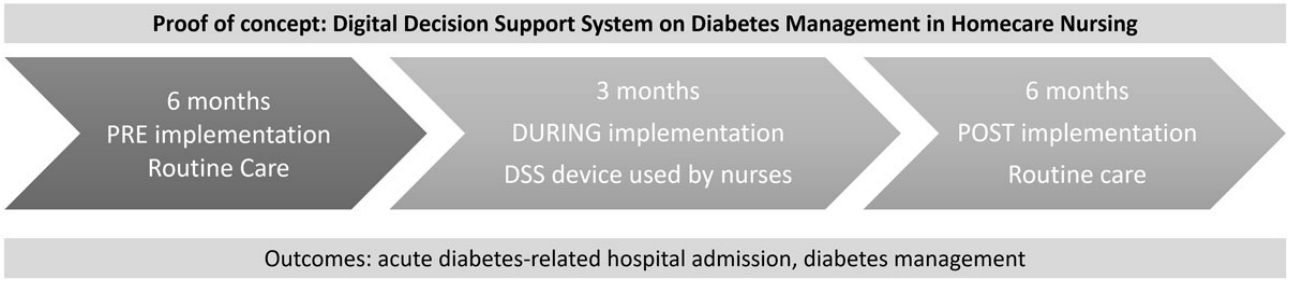
Innovative point-of-care digital decision support systems (DDSSs) are increasingly recognized as useful tools to facilitate evidence-based care specifically in people of older age and with impaired health status and more pronounced comorbidity profiles [14,15]. Evidence from randomized controlled trials has demonstrated that technology-supported and digitally enabled care interventions can improve clinical outcomes in chronic diseases, including diabetes [16]. Similarly, telehealth and structured chronic disease management approaches have been shown to improve care processes and reduce health care use [17]. Developments in glycemic care include computerized order sets, blood glucose data networks with visualization, case-finding tools, insulin calculators, electronic treatment protocols, titration algorithms, and alert systems [18,19]. For example, the DDSS GlucoTab supports basal-bolus insulin titration workflows by structuring care processes and offering standardized recommendations in the hospital setting. While such systems are often well established in hospitals [20-22], it remains unclear whether these tools can be effectively used in home care nursing. Although evidence from hospital and telehealth settings supports the effectiveness of such digital interventions, their transferability to home care nursing environments remains underexplored [17]. Each tool must be tested in its new care setting as it cannot be assumed that the systems designed for hospitals will function seamlessly in home care nursing.

To address this gap, DDSSs designed for nursing care are gaining more and more attention. A recent review highlights the importance of integrating nurses into every stage of innovation design and implementation to preserve care-centric perspectives [23]. Current desktop tools and mobile apps for the nursing care of older adults use nursing process frameworks to personalize interventions, showing a trend toward smart, home-based support systems [24]. These findings align with broader themes of nurse empowerment and digitally supported, person-centered care.

Objectives

This study aimed to assess the effects of a multicomponent intervention including a DDSS on diabetes management by assessing diabetes-related glycemic management outcomes and hospital admissions in older adults with type 2 diabetes receiving home care nursing. This study was guided by the following research questions: (1) How does the implementation of a nurse-led DDSS affect glycemic outcomes across pre-, during, and postimplementation phases? (2) How does the DDSS influence diabetes-related hospital admissions in older home-cared adults? Outcomes were examined over 3 phases: 6 months before implementation, 3 months during implementation, and 6 months after implementation of the nurse-guided DDSS for insulin therapy.

XSL•FO
RenderX



Methods

Overview

This study was conducted and reported as a prospective quasi-experimental feasibility and implementation study in a real-world setting. Reporting followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines where applicable given the nonrandomized observational design. Relevant elements from the CONSORT-AI (Consolidated Standards of Reporting Trials–AI) extension were considered for the description of the DDSS [25]; however, the CONSORT-AI was not fully applicable due to the nonrandomized, nontrial design of this study. Furthermore, GlucoTab (decide Clinical Software GmbH) is a rule-based clinical decision support system and not a machine learning–based AI system.

Following the overall study design, assessments were conducted at 3 predefined time points: before implementation (6 months), during implementation (implementation phase with active DDSS use; 3 months), and after implementation (postimplementation follow-up phase after DDSS discontinuation; 6 months; Figure 1). This study was conducted in Graz, Austria, at 2 home care nursing sites of the Austrian Red Cross, a private, nonprofit organization.

Figure 1. Study design to assess outcomes in the pre-, during, and postimplementation phases of a digital decision support system (DDSS) for diabetes management in home care nursing.

Participants

A total of 9 individuals with type 2 diabetes were enrolled in the study. All 9 participants were assessed before implementation and during implementation. Only 8 participants were assessed after implementation as 1 participant died in the postimplementation phase.

Eligible participants were adults with type 2 diabetes treated with insulin therapy who received home care nursing from the Austrian Red Cross. Recruitment took place at 2 Austrian Red Cross home care sites. Local home care teams identified patients who met the predefined eligibility criteria and informed the study team about potentially eligible individuals. The most important exclusion criteria were medical conditions interfering with study participation or safety, other forms of diabetes (eg, type 1 diabetes), mental incapacity to provide consent, or terminal illness.

Study Intervention

The intervention involved a multicomponent restructuring of care delivery, including structured nursing training, a DDSS, physician-guided initiation of insulin therapy, and standardized insulin titration protocols. The DDSS used (GlucoTab) included decision support for health care professionals regarding automated suggestions for insulin dose, adjustments for basal insulin therapy, and changes in the insulin regimen. The DDSS also included suggestions for blood glucose measurement frequency, workflow support through visualization of open tasks, and support with a documentation interface. In a previous study, the basal insulin algorithm was specifically adapted for geriatric individuals [26]. An evidence-based version developed in line with international guidelines [3] was digitally implemented integrated into the GlucoTab software, with the system and workflows tailored to the routines of home care nursing. Importantly, the system empowers nurses to act directly in the individual's home based on current blood glucose values independently of physician availability, including evenings and weekends, when medical support is often limited.

Before implementation, home care nurses and supervising study physicians participated in a structured group training covering the intervention.

During the implementation phase of the intervention, the study physicians prescribed the initial insulin regimen, and subsequent dosing was managed by home care nurses using GlucoTab. The DDSS allows physicians to either independently determine the initial basal insulin dose for participants (already receiving insulin therapy) or request an algorithm-generated dosing recommendation for participants newly initiated on insulin therapy. In both cases, the final decision on initial insulin therapy remains physician led. GlucoTab automatically flags unsafe situations (eg, low blood glucose values) and ensures physician review when necessary. The DDSS automatically records all generated recommendations and corresponding nursing actions, enabling objective and reproducible calculation of adherence rates [20-22]. The system uses a mobile client-server architecture connected via a secure Long Term Evolution network to a centralized, secure server environment hosted on the premises of Joanneum Research Forschungsgesellschaft mbH (Austria).

During the implementation phase, nurses accessed GlucoTab via standard tablet devices using individual secure log-ins during home care visits. The system does not require dedicated medical hardware and was used directly at the point of care to document blood glucose values, insulin administration, and relevant clinical information. On the basis of the entered data, GlucoTab generated individualized, algorithm-based decision support recommendations for insulin management. Nurses reviewed

XSL•FO
RenderX

these recommendations and integrated them into their clinical decision-making process while retaining responsibility for the final insulin dosing and administration decision.

During the pre- and postimplementation phases, participants received routine care, which encompassed paper-based diabetes management, including diabetes therapy, and the frequency of blood glucose measurements was prescribed by the treating general practitioner. Home care nurses performed blood glucose monitoring and administered diabetes therapy as prescribed. Importantly, the postimplementation phase represents routine care after DDSS discontinuation rather than a genuine return to baseline conditions as training effects and workflow changes established during implementation may persist into the postimplementation phase.

Assessments and Data Analysis

In all phases, clinical and demographic data and diabetes management data (blood glucose values, measurement frequency, insulin dosing and injection, general practitioner contacts, and diabetes-related hospital admissions) were collected from (electronic) health records and paper-based nursing documentation of the home care nursing provider.

Hypoglycemia was defined as capillary blood glucose values below 54 mg/dL and/or hypoglycemic events requiring third-party assistance. Hypoglycemic events were identified from nursing documentation and blood glucose records. Continuous glucose monitoring was not available in this study.

During the implementation phase, additional data regarding diabetes management were recorded directly in the DDSS for nurses. Clinical and demographic data were digitally entered into electronic case report forms (OpenClinica; OpenClinica, LLC) and spreadsheets by a qualified researcher. Quality control was ensured by applying a 4-eye principle to verify completeness and accuracy.

Nurse acceptance was operationalized as adherence to DDSS-generated recommendations and was objectively measured using automatically logged system data capturing nurse responses and actions within the DDSS.

Data analysis was performed using the statistical program SPSS Statistics (version 26; IBM Corp) and Microsoft Excel. Data were first summarized using descriptive statistics. For numerical data, depending on the distribution, means and SDs; medians; minimum, maximum, and range; and quartiles were calculated. Categorical data are presented as absolute and relative frequencies. Due to the quasi-experimental feasibility and implementation design of the study, no inferential statistical analyses and no sample size calculation were conducted.

Demographics

Nine participants receiving home care nursing were included (n=5 women; mean age 77, SD 10 years; mean hemoglobin A_{1c} [HbA_{1c}] 59.5, SD 12.8 mmol/mol; mean BMI 27.7, SD 4.7 kg/m^2 [before implementation]). Before implementation, 4 participants had diabetes-related comorbidities: retinopathy (n=2), neuropathy (n=3), and nephropathy (n=3).

The 9 participants completed all 3 study phases as per the protocol. One participant was hospitalized (unrelated to the study) and withdrew but was included in the analysis as intervention duration was completed. One participant died during the postimplementation phase for reasons unrelated to the study.

Ethical Considerations

This study was approved by the Ethics Committee of the Medical University of Graz (approval numbers EK 30 - 287 ex 17/18 and EK 31 - 522 ex 18/19) and relevant legal authorities. It was conducted in compliance with good clinical practice and the principles of the Declaration of Helsinki.

All eligible patients identified were invited to participate; all provided informed consent and were enrolled in the study. To ensure confidentiality, participants were assigned unique study identification numbers, preventing traceability of personal data. No participant compensation was provided.

Results

Diabetes-Related Hospital Admissions

During the preimplementation phase, 5 diabetes-related emergency admissions were documented in 4 participants, resulting in 4 hospitalizations. In the postimplementation phase (after DDSS discontinuation), 4 diabetes-related emergency admissions occurred in 2 participants, leading to 1 referral to the diabetes outpatient clinic and 2 hospitalizations. No diabetes-related emergency admissions or hospitalizations were observed during the implementation phase (Table 1).

>180	60.8	22.1 (219/ 992)	28.8
HbA_{1c}[d] (mmol/mol), mean (SD)	59.5 (12.8)	56.5 (12.4)	—[e]

[a]One participant died during the postimplementation phase.

[b]Bolus insulin for main meal or for correctional insulin.

[c]Absolute frequencies (n/N) cannot be provided for before and after implementation because the original dataset is currently unavailable.

[d]HbA_{1c}: hemoglobin A_{1c}.

[e]HbA_{1c} was not available in the postimplementation phase.

Hyperglycemia was the reason for referral in 8 of the 9 diabetes-related emergency admissions; the remaining diabetes-related emergency admission was due to hyperglycemia. The length of inpatient stays ranged from 8 to 15 days, with a median of 9 days.

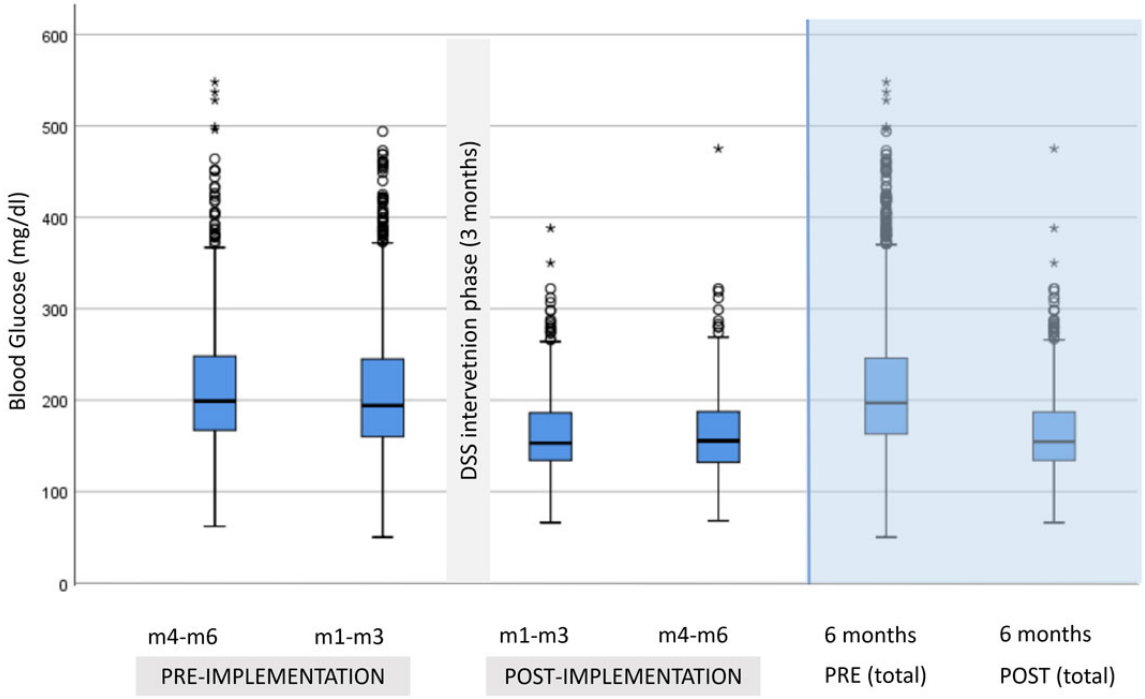
Nurse-Led Diabetes Processes in Home Care

Table 1 summarizes diabetes management and outcomes across the 3 study phases. In the preimplementation phase, 77.8% (7/9) of the participants received premixed insulin, including 22.2% (2/9) with additional bolus insulin. A total of 22.2% (2/9) of the participants received basal insulin, of whom 1 also received bolus insulin. After study completion, all participants (8/8, 100%) were treated with basal insulin, with 37.5% (3/8) additionally receiving bolus insulin for correcting hyperglycemia. In 62.5% (5/8) of the participants, the suggested basal insulin titrations were implemented by general practitioners; in 37.5% (3/8) of the participants, the recommended corrections were not adopted during the postimplementation phase.

During the implementation phase, therapy adjustments based on DDSS recommendations were made on average 9 times in the 3 months (up to 18 times). The number of diabetes-related home care nursing visits decreased from 1.81 to 1.01 per day when comparing the pre- and during implementation phases, largely due to reduced necessity of blood glucose checks.

In total, 35 diabetes-related contacts with general practitioners were documented, of which 19 (54.3%) occurred in the 6-month preimplementation phase and 16 (45.7%) occurred in the postimplementation phase, indicating a slight reduction after the implementation phase. In the preimplementation phase, 36.8% (7/19) of the general practitioner contacts were due to a planned checkup, 57.9% (11/19) were for therapy adjustment, and 5.3% (1/19) were for HbA_{1c} determination. In the postimplementation phase, 31.3% (5/16) of the general practitioner contacts were due to planned controls, and 68.8% (11/16) were due to therapy adjustment. During the implementation phase, nurses contacted the outpatient diabetes clinic via telephone as suggested by the DDSS for receiving medical advice, but no quantitative data were systematically recorded in this phase.

Glycemic Outcomes



Mean morning blood glucose values decreased from 212 (SD 72) mg/dL before implementation to 162 (SD 42) mg/dL after implementation. No hypoglycemic events requiring third-party assistance were observed during any study phase. Biochemical hypoglycemia (<54 mg/dL) was rare, with 0.1% of glucose measurements below this threshold in the preimplementation phase and no values below 54 mg/dL during implementation or after implementation. The proportion of blood glucose measurements within the prespecified target range (70 - 180 mg/dL) was 39.0% before implementation, 77% (764/992) during implementation, and 70.8% after implementation,

XSL•FO
RenderX

whereas measurements above 180 mg/dL were 60.8%, 22.1% (219/992), and 28.8%, respectively (n/N values were only available for the during-implementation period).

The distribution of blood glucose values over time showed a clear trend toward improved glycemic control (Figure 2, right panel). Higher mean values and wider variability were observed in the preimplementation phase. In contrast, a marked reduction in median blood glucose levels and variability was found in the implementation phase. This improvement was sustained during the following 3 months, with the 6-month postimplementation phase showing improved glycemic control compared to the 6-month preimplementation phase.

Figure 2. Box plots for blood glucose values in the pre- and postimplementation phases (boxes represent the IQR with the median, whiskers indicate 1.5 times the IQR, dots indicate outliers [1.5 - 3 times the IQR], and stars indicate extreme outliers [>3 times the IQR]). The figure shows longitudinal glucose measurements over time, with repeated measurements from the same participants reflecting real-world glucose monitoring. DSS: decision support system.

User Acceptance

In 88.9% (8/9) of cases, physicians chose to set the initial basal insulin dose independently without using the DDSS-generated recommendation (all participants already received insulin therapy before GlucoTab implementation). Adherence to the DDSS recommendations by nurses was high: 94.7% (552/583) for blood glucose measurement frequency, 95.8% (295/308) for basal insulin dose adjustment, 99.7% (764/766) for basal insulin injections, 97.9% (142/145) for bolus insulin injections, and 100% (231/231) for titration time points.

Discussion

Principal Findings

This prospective quasi-experimental feasibility and implementation study suggests that integration of a DDSS into home care nursing corresponded with improved diabetes management outcomes over time. During the implementation of the DDSS, emergency department visits and hospitalizations were reduced, highlighting improved patient safety and favorable clinical outcomes. Glycemic control improved over time, while therapy appeared simplified and nursing visits decreased, suggesting potential improvements in efficiency and resource use.

Diabetes management in home care or long-term care facilities is often challenged by the complexity of insulin regimens used in older adults, the high variability of daily blood glucose levels, and the frequent need for medical decisions. Many older adults with diabetes receive once- or twice-daily basal or premixed insulin, which still requires regular dose adjustments [8,27]. However, in clinical practice, contacts with general practitioners occur infrequently, dose adaptations are often delayed, and nurses are frequently forced to act autonomously without formal medical orders. As a consequence, clinical uncertainties can lead to avoidable emergency department transfers or hospital admissions [8]. DDSSs directly address these challenges by providing structured, algorithm-guided titration that supports timely and safe decisions at the point of care.

Our study findings extend the evidence base for algorithm-guided diabetes management using GlucoTab as initially demonstrated in hospitalized patients [20-22], where the decision support system guided insulin dosing, achieving effective glycemic control with reduced hypoglycemia and appropriate adherence to dose suggestions. A recent comprehensive review emphasizes that technological solutions, including connected insulin pens, continuous glucose monitoring, automated insulin delivery systems, and other digital tools, play an increasingly important role in the care of older adults with diabetes. Through reduction of blood glucose

XSL•FO
RenderX

variability and hypoglycemia risk, as well as by improving quality of life and reducing hospital admissions, such technologies support safe and effective long-term diabetes management in older, multimorbid populations [15]. This broad evidence for diabetes technology in older adults reinforces the relevance and potential impact of GlucoTab in home care nursing.

Beyond home care, randomized controlled trials have shown that nurse-assisted insulin titration can safely improve glycemic control. For example, decision-supported telephone coaching by diabetes specialty nurses enabled individuals to self-titrate basal insulin safely, resulting in greater HbA_{1c} reductions without increasing hypoglycemia compared to usual care [28]. This previous study underscores that combining decision support with nurse engagement meaningfully improves glycemic outcomes in noninstitutionalized individuals, supporting our findings from this quasi-experimental feasibility and implementation study in home care nursing.

The high acceptance levels that we observed among nurses, with adherence rates exceeding 94%, align with nursing-focused digital health literature. These findings are in line with evidence that nurse-led care models improve chronic disease outcomes and strengthen care quality in primary care settings [10]. Recent studies published in *JMIR Nursing* and *JMIR Diabetes* underscore the importance of implementing user-friendly digital tools in fostering adherence and enabling nurse-led care innovations [29,30]. Usability is a key concept in the evaluation of digital health technologies and can be defined as the extent to which a system enables users to achieve specified goals with effectiveness, efficiency, and satisfaction. Importantly, usability is influenced by the users, tasks, and context of use, which is particularly relevant in home care settings where clinical decision-making occurs in complex real-world environments [31]. Established usability evaluation methods include inspection-based approaches and user-centered evaluation techniques that are used to identify usability problems and barriers to system use during development and implementation [32]. However, formal usability testing was not conducted in the present study. Recent digital health research further emphasizes that successful implementation of health technologies requires the combined evaluation of usability, user experience, and implementation outcomes as these factors jointly influence adoption, safety, and long-term sustainability [33]. This supports the notion that the DDSS not only augments clinical outcomes but also empowers nursing autonomy and confidence, allowing nurses to integrate the DDSS seamlessly into daily routines and care activities and spend more time on direct patient care rather than administrative tasks or frequent coordination with general practitioners.

The observed reduction in home nursing visits and the simplification of therapy processes through GlucoTab suggest considerable potential for cost savings and efficiency gains in home care nursing services. At the same time, the DDSS strengthens nurses' autonomy and supports safe, evidence-based decision-making without continuous physician oversight. This is in line with international guidelines advocating for structured nurse-led insulin titration under standardized protocols (eg, the Irish national insulin titration guideline for nurses) [34]. These effects align with broader health system goals of optimizing resource use without compromising quality, a particularly relevant consideration in international settings with varying home care constraints. Similar findings have been reported in other studies. A systematic review demonstrated that telehealth interventions for communication between individuals with type 2 diabetes and health care professionals significantly improved glycemic control, with 80% of included studies also showing potential for cost reduction [35]. Another study reported a reduction in overall health care costs of approximately US $24,000 over 7 months through telehealth-based diabetes management, highlighting substantial savings for the health care system [36].

Recent advances in AI and digital health research further contextualize these findings. Emerging AI-enabled decision support prototypes for basal insulin titration have shown promising usability and safety in hospital and early primary care evaluations, indicating that nurse-in-the-loop models could further enhance precision and individualization of insulin therapy in home care settings. Integrating such tools may help reduce practice variation, strengthen guideline adherence, and potentially open pathways for decision support in broader chronic disease management beyond insulin therapy [24,37-39].

These findings suggest the potential of digital interventions such as GlucoTab not only to improve clinical outcomes but also to enhance efficiency and reduce costs in home care nursing services by minimizing the need for frequent coordination with general practitioners, enabling nurses to work more autonomously with decision support, and reducing dependence on continuous medical orders.

Limitations and Future Directions

The relatively small sample size and observational design may limit the generalizability of our findings. The observational pretest-during-posttest design without a control group limits causal inference. All outcomes should be interpreted as descriptive and hypothesis generating rather than causal evidence of effectiveness. A key limitation is that the postimplementation phase does not reflect a return to baseline as participants and care processes may have been influenced by DDSS implementation, structured training, and persistent workflow adaptations. Pretest-posttest comparisons should thus not be interpreted as changes between fully independent states.

The variation in the lengths of the study phases (6-3-6 months) and the limited external validity due to participation of only two study sites in a single region also constrain the transferability to other settings. Long-term sustainability of the observed improvements, therefore, requires confirmation through larger, ideally randomized studies conducted across diverse health care systems.

Future research should focus on (1) evaluating cost-effectiveness through detailed economic analyses; (2) testing scalability and adaptation of GlucoTab in varied international home care models; and (3) exploring the effects of DDSSs on broader populations, including non–insulin-dependent individuals with type 2 diabetes or other chronic diseases and further

XSL•FO
RenderX

patient-centered clinical end points (eg, mortality and disability). Furthermore, glycemic control might be more intensively supervised by using (blinded) continuous glucose monitoring systems in future studies to obtain a broader picture of the efficacy of such a DDSS.

Relevance to Clinical Practice for the Wider Global Clinical Community

This study provides in-depth insights into the quality of diabetes management for people receiving home care nursing, a population that is often underrepresented in research. It generates evidence to guide policymakers and nursing care managers in designing strategies that ensure high-quality diabetes care in home care settings by strengthening the role and competencies of nursing staff. Furthermore, it presents an exemplary digital decision support solution that empowers nurses, enhances the quality of care, and promotes interdisciplinary collaboration with general practitioners, thereby offering a transferable model for other health care systems.

Conclusions

In the long term, DDSSs have the potential not only to reduce costs in the home care setting but also to enhance the evidence-based quality and safety of care for people with type 2 diabetes. This quasi-experimental feasibility and implementation study provides the first evidence that a nurse-led DDSS such as GlucoTab can safely and effectively improve glycemic control in older adults receiving home care nursing, reduce hospitalizations, simplify therapy, and enhance nurse autonomy. Given its feasibility, this approach could empower nurse-led diabetes management, optimize resource use, and improve outcomes for people with diabetes in diverse health care settings. Collectively, these findings highlight the potential of digitally supported, nurse-driven interventions as scalable, patient-centered solutions for managing complex diabetes care in community and long-term care environments.

Abstract

Background: Machine learning (ML) has been demonstrated to enhance health care cost prediction by handling high-dimensional data and identifying complex patterns. However, current risk-adjustment models rarely incorporate structured nursing information derived from the nursing process. This information captures care needs and human responses to health problems.

Objective: This study aimed to evaluate the impact of integrating nursing process data into ML-based predictive models of individual health care costs, including cost component analyses, compared with models based solely on sociodemographic, clinical, and morbidity-related variables.

Methods: A retrospective observational study was conducted using a population-based cohort of 1,691,075 individuals aged 15 years or younger who were registered with the Canary Islands Health Service. Predictors were derived from data available up to 2017 and included sociodemographic and clinical variables, Adjusted Morbidity Groups, health care use, and structured nursing records (Functional Health Patterns [FHP], North American Nursing Diagnosis Association [NANDA], Nursing Outcomes Classification [NOC], and Nursing Interventions Classification [NIC]). Predictive models were developed using feedforward neural networks and extreme gradient boosting; predictions were combined using an ensemble approach. An autoencoder was applied as a dimensionality-reduction technique for the nursing variables. Model performance with and without nursing variables was compared on total cost and individual cost components, and the coefficient of determination (R^2) was used on the test set.

Results: Including the nursing methodology yielded small numerical increases in predictive performance. With respect to total cost, the ensemble model improved the R^2 from 0.5023 to 0.5058 when the nursing variables were added. Although directionally consistent, these gains were limited in magnitude. In the component-level analyses, performance gains were observed in hospital care (R^2=0.2396) and pharmaceutical costs (R^2=0.6631). Reducing 789 nursing variables to 16 latent dimensions using an autoencoder substantially simplified the feature space, with predictive performance remaining broadly comparable but without a substantial additional gain.

Conclusions: Integrating structured information from the nursing process is associated with small incremental improvements in ML-based predictive models and complements commonly used sociodemographic, clinical, and morbidity variables. The systematic incorporation of nursing data into predictive tools may contribute to more accurate health care cost prediction and support more holistic, person-centered approaches.

Introduction

Efficient allocation of resources in health care systems requires accurate and reliable estimates of future expenditure, particularly in a context characterized by budgetary constraints and increasing care complexity. Inaccurate cost estimation may lead to inefficient decision-making and compromise the financial sustainability of health services [1-3]. In this context, machine learning (ML) has gained relevance because it provides tools capable of identifying complex patterns, handling missing values, and improving predictive accuracy compared with traditional statistical methods [4-9].

Within the field of cost prediction, risk-adjustment systems such as Adjusted Clinical Groups (ACGs) [10], Clinical Risk Groups (CRGs) [11], and Adjusted Morbidity Groups (AMGs) [12] play key roles in population risk stratification by anticipating care needs and budgetary requirements. These models have been widely used to estimate costs associated with different patient profiles, and their performance is typically assessed using metrics such as the coefficient of determination (R^2) [13]. In Spain, the AMG risk-adjustment system explains approximately 31% of the variability in total health care costs, suggesting substantial room for improvement [14]. In response to these limitations, ML techniques have increasingly been applied to risk-adjustment frameworks because of their greater capacity to identify complex patterns in large datasets. The use of neural networks, boosting models, and penalized regression approaches has been shown to improve predictive accuracy [13,15]. Methods such as neural networks and ridge regression have shown good performance in cost estimation using historical data [6].

Moreover, the types of data incorporated into risk-adjustment models have evolved. Electronic health records, which capture sociodemographic data and multiple dimensions of health status, are a rich source of information. Supervised learning models are particularly well suited for analyzing these data, as they can detect latent interactions and manage nonnormally distributed variables, such as health care costs. Leveraging these data allows more accurate estimation of health care resource use and identification of relevant patterns of association [16].

In this context, Bertsimas et al [17] reported that the accuracy of cost prediction models depends largely on the quality, completeness, and standardization of the data used and suggested that incorporating new variables that more faithfully reflect actual care delivery may enhance predictive performance. However, most predictive models, including those based on variables commonly used in ACG, CRG, and AMG risk-adjustment systems, rely primarily on sociodemographic and clinical variables such as gender, age, comorbidities, procedures, and pharmaceutical expenditures [11]. The inclusion of social determinants has been shown to significantly improve the predictive capacity of these models. For example, a recent study reported that incorporating such factors increased the R^2 from 0.327 to 0.388, reducing estimation errors by 3.5 million dollars per 10,000 individuals added [18]. Similarly, factors such as low income, educational level, food insecurity, or housing instability have been significantly associated with high-cost patient profiles [19], although these variables are rarely included in cost prediction models. Harnessing the richness of electronic health record data, together with big data analytics in health care, offers opportunities to improve outcomes and reduce costs [20].

Despite these advances, most predictive models continue to exclude information derived from the nursing process, even though it has the potential to capture essential aspects of health status and service use [2,6]. The incorporation of standardized nursing terminologies such as the North American Nursing Diagnosis Association (NANDA), the Nursing Outcomes Classification (NOC), and the Nursing Interventions Classification (NIC) could substantially enhance predictive models by capturing the impact of nursing interventions. These terminologies, which have been progressively integrated into electronic health records, enable systematic characterization of nursing practice, facilitate assessment of its impact on health outcomes, and support the development of robust predictive models [21]. Understanding and quantifying nursing care in a systematic and effective manner may contribute to optimizing resource allocation and improving health system sustainability [22]. In this context, Functional Health Patterns (FHP) described by Gordon provide a nursing assessment framework that offers a holistic view of patient health, encompassing physical, emotional, and social dimensions. Although this framework may add value in terms of efficiency and resource management, its impact on health care cost prediction has rarely been explored [23]. Nevertheless, a previous study revealed that more than 21% of the variability in total health care costs could be explained by a model including gender, age, and variables derived from the nursing process (NANDA, NOC, NIC, and FHP) [24]. This study adds a comparison between nursing process data and the clinical, sociodemographic, and morbidity-related variables commonly used in cost prediction. It also extends the analysis to partial cost components and explores dimensionality reduction.

Recent literature has highlighted that incorporating additional layers of information, such as social determinants or measures of well-being, significantly improves the performance of health care cost prediction models and helps correct biases affecting vulnerable populations [18,19]. In parallel, the inclusion of structured nursing data has been shown to provide valuable insights into the impact of nursing practice on health outcomes and patient safety [21]. However, to date, no studies have systematically integrated information derived from the nursing process into ML-based models specifically designed for health care cost prediction.

Against this background, leveraging the potential of nursing big data and integrating it with advanced ML techniques represents an opportunity to improve risk-adjustment systems, enhance population stratification, and support more efficient and equitable resource allocation. Accordingly, the aim of this study was to evaluate the impact of integrating nursing process data into ML-based predictive models of individual health care costs, including cost component analyses, compared with models based solely on sociodemographic, clinical, and morbidity-related variables.

Methods

Study Design and Setting

The present study forms part of a longitudinal research program based on a single population cohort that aims to understand the determinants of health care costs from a comprehensive perspective. In the first phase, individual health care costs were estimated, and their variability was analyzed according to AMG using multiple linear regression [14]. In the second phase, ML-based predictive models were developed to explain the variability in total health care costs, incorporating information derived from the nursing process [24].

The present (third) phase extends this analytical framework by focusing specifically on the contribution of nursing process variables (NANDA, NOC, NIC, and FHP) to health care cost prediction. To this end, a retrospective, observational, and analytical study was conducted using data from multiple health care information systems. The study was carried out in the Autonomous Community of the Canary Islands (Spain) using data from 2017 and 2018. The predictor variables were derived from data available up to 2017, whereas health care costs were measured for 2018, thus ensuring appropriate temporal ordering for predictive modeling.

Ethical Considerations

In accordance with the Declaration of Helsinki and Spanish legislation, this study was approved by the Clinical Research Ethics Committee of the Dr. Negrín University Hospital of Gran Canaria (date: January 29, 2021; code: 2021-037-1). All applicable ethical and regulatory principles for studies using secondary health data were observed.

Study Population

The study population included all individuals aged 15 years or older who were registered in the Canary Islands Health Service health care card database as of December 31, 2017 (N=1,691,075). The entire target population was included. Individuals covered by mutual insurance schemes were excluded; these correspond to public-sector employees whose health care and social care are managed outside the Canary Islands Health Service.

Variables

Predictor variables were derived from data available up to 2017 and included sociodemographic, clinical, morbidity-related, and nursing process information. The sociodemographic variables comprised age, gender, type of affiliation with the social security system, and the percentage of pharmaceutical copayment. Clinical variables included a Barthel Index score greater than 60, a Pfeiffer test score of 5 or lower, 2 or more hospital admissions in the previous 12 months, and the number of prescribed active pharmaceutical ingredients. Morbidity-related variables were obtained from the AMG system and included the complexity weight and morbidity group.

Nursing process variables were also incorporated and consisted of 44 variables derived from the assessment of the 11 FHP (with 4 possible outcomes per pattern), as well as 211 NANDA nursing diagnoses, 388 NOC outcomes, and 558 NIC interventions. The large number of variables reflects the conceptual structure of nursing data, which captures complementary dimensions of human responses, outcomes, and interventions; therefore, regularization and hyperparameter tuning were applied to mitigate the dimensional burden.

The primary outcome was total health care cost per individual in 2018. This was calculated as the sum of the costs associated with primary care and specialist consultations, emergency department visits, hospital admissions, major ambulatory surgery in public and contracted centers, and pharmaceutical dispensing (Multimedia Appendix 1). In addition, a cost component analysis was conducted for different care settings (primary care, hospital care, and contracted care) and service types (hospital admissions, outpatient consultations, and emergency department visits).

Data Sources

Data were obtained from the following information systems: the Canary Islands Health Service health care card database (sociodemographic variables), primary care electronic health records (medical and nursing consultations and nursing process variables), hospital electronic health records (hospital consultations and emergency department visits), the Minimum Basic Dataset of the Hospital Activity Registry (hospital admissions and surgical procedures), the Hospital Contracted Care Information System (activity in contracted centers), and the electronic prescribing system of the Canary Islands Health Service (pharmaceutical dispensing). All databases were linked using a unique, encrypted clinical identifier for each individual.

Data Preprocessing and Analytical Strategy

Prior to analysis, numerical variables (age and AMG complexity weight) were standardized. Cost variables were transformed using natural logarithms to approximate normal distributions. Nursing diagnoses (NANDA), outcomes (NOC), and interventions (NIC) with a prevalence lower than 1 per 10,000 individuals were excluded, as they provided limited information, had a high proportion of zero or missing values, and unnecessarily increased model dimensionality. This threshold was applied pragmatically, as no comparable reference studies were identified, with the aim of filtering infrequent variables and thereby reducing sparsity and computational burden.

After the data were cleaned, a descriptive analysis of the study population was performed. As the entire population was included, no statistical inference techniques were applied. The analytical focus was exclusively on the development and evaluation of predictive models.

Two ML algorithms capable of handling large-scale, high-dimensional health care data were evaluated using complementary modeling approaches. First, a feedforward neural network was implemented [25], which consisted of interconnected layers designed to capture nonlinear relationships and latent patterns. Second, extreme gradient boosting (XGBoost) [26], a gradient-boosted decision tree algorithm recognized for its efficiency, accuracy, and ability to handle missing values and skewed distributions, was applied. Predictions from both models were combined using an ensemble approach based on their averaged outputs to improve robustness [27].

XSL•FO
RenderX

The dataset was randomly split into training (80%), validation (10%), and test (10%) subsets. During model training, the mean squared error (MSE) was used as the optimization metric, while overall performance was assessed using the coefficient of determination (R^2). Because health care cost data were highly skewed, the outcome was log-transformed before modeling, and both model fitting and performance metrics, including R^2, were calculated on that log-transformed scale. R^2 was used as the primary metric to compare relative model performance across the different predictor sets. Given the very large cohort size, a single training, validation, or test split was considered sufficient for initial model development and evaluation, as both the validation and test subsets each included more than 160,000 individuals. For the feedforward neural network, the final architecture consisted of 4 hidden dense layers (128, 64, 32, and 16 units) with rectified linear unit activation and L1 regularization (l1=0.0000625; l2=0). The model was trained using the root mean square propagation optimizer with a learning rate of 0.0005, a batch size of 64, and a maximum of 60 epochs. Early stopping was applied based on the validation R^2 (monitor=val_r_square, mode=max, and patience=5), and the best model weights were restored. For XGBoost, the final model was trained with a learning rate of 0.0960, a maximum tree depth of 10,500 estimators, a subsample of 0.9413, full column sampling per tree (colsample_bytree=1.0), L1 regularization (reg_alpha=10.0), and L2 regularization (reg_lambda=0.001). Hyperparameter optimization was conducted on the validation set, and the final model performance was evaluated exclusively on the test set. A fixed random seed of 42 was used to ensure reproducibility.

The analytical strategy involved 3 stages. First, baseline models excluding the nursing process variables and extended models including these variables were developed and compared for total health care cost prediction. Second, cost component analyses were conducted at both the care setting level (primary care, hospital care, and contracted care) and the service level (hospital admissions, outpatient consultations, and emergency department visits), and model performance was compared with and without the nursing process variables. Third, an autoencoder was applied to reduce the dimensionality of the nursing process variables, as the feature block was high-dimensional and predominantly binary, making a more flexible nonlinear approach preferable to the conventional principal component analysis. This neural network architecture compresses high-dimensional input data into a lower-dimensional latent representation and reconstructs it, thereby enabling the identification of unsupervised latent patterns [28]. Autoencoders have previously been applied in hospital cost prediction studies [29]. All analyses were performed using Python version 3.10.8, with the *pandas*, *NumPy*, *scikit-learn*, *TensorFlow*, and *XGBoost* libraries.

Results

Characteristics of the Study Population

The study included 1,691,075 individuals aged over 15 years, including 863,071 (51.0%) women; the mean age was 46.6 (SD 17.9) years, and 17.4% (n=294,077) were older than 65 years. The mean AMG index weight was 5.82 (SD 5.89) points, which was higher in women (6.25, SD 6.06) than in men (5.10, SD 5.62) and increased with age (Spearman ρ=0.47). A total of 216,630 (12.8) women and 175,536 (10.4) men were pensioners. The mean number of prescribed medications was 4.35 (SD 5.10), with higher values observed in women.

Overall, 22,800 (1.3%) individuals had 2 or more hospital admissions in the previous year, 6308 (0.4%) had a Barthel Index score greater than 60, and 7271 (0.4%) demonstrated cognitive impairment (Pfeiffer score≥5). Nursing records (FHP, NANDA, NOC, and NIC) were present for 57.9% (980,437/1,691,075) of the population, although only 2.7% (46,380/1,691,075) had completed the full nursing process. On average, 3.84 (SD 3.58) FHP were assessed per person, together with 3.07 (SD 2.9) NANDA nursing diagnoses, 2.77 (SD 2.96) NOC outcomes, and 4.12 (7.04) NIC interventions.

The mean cost per patient was €1283.08 (SD €3007; €1=US $1.19 as of December 31, 2017), with higher values observed among women. Hospital admissions and consultations accounted for the highest cost components. Costs were heterogeneously distributed across care settings, with those for consultations (mean €355.07, SD €586.87) and pharmaceutical dispensing (mean €345.53, SD €946.09) being especially notable. Table 1 presents details of the variables included in the models; the complete cohort profile can be found in previous publications [14,24].

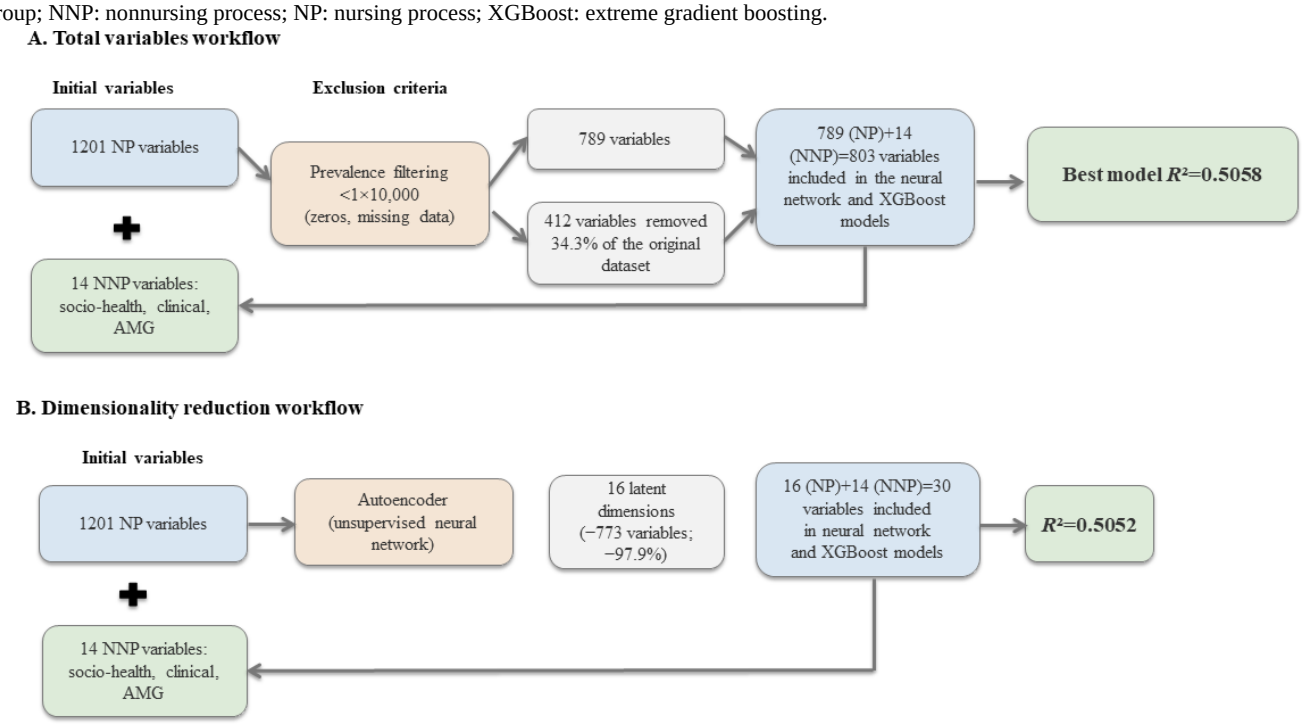
[c]FHP: Functional Health Pattern.

[d]NANDA: North American Nursing Diagnosis Association.

[e]NOC: Nursing Outcomes Classification.

[f]NIC: Nursing Interventions Classification.

[g]Health care cost components are presented by care setting (primary care, hospital care, and contracted care) and by service type (hospital admissions, outpatient consultations, and emergency department visits), as well as pharmaceutical dispensing.



Predictive Performance of the Baseline and Extended Models for Health Care Cost Prediction

The neural network architecture with the best performance was a feedforward network with 4 hidden layers (128, 64, 32, and 16 nodes) and an output corresponding to the logarithm of the total cost. For the XGBoost model, Bayesian hyperparameter optimization was applied to identify the combinations with the best performance, and an ensemble model was subsequently generated by averaging the predictions.

The initial feature set included sociodemographic and clinical variables, together with 1201 nursing process variables. After those with a positive prevalence of fewer than one per 10,000 patients were excluded, 789 nursing variables and 14 sociodemographic, clinical, and AMG system variables were retained (Figure 1).

XSL•FO
RenderX

Figure 1. Workflow of nursing-variable selection and dimensionality reduction for the neural network and XGBoost models. AMG: Adjusted Morbidity Group; NNP: nonnursing process; NP: nursing process; XGBoost: extreme gradient boosting.

In the baseline models, excluding the nursing variables, the R^2 was 0.4996 for the neural network, 0.5030 for XGBoost, and 0.5023 for the ensemble model. After the nursing process variables were incorporated, the predictive performance increased to 0.5026 (MSE 3.8561), 0.5065 (MSE 3.7936), and 0.5058 (MSE 3.7981), respectively, indicating improvements across all 3 algorithms.

Predictive Performance by Cost Component According to Care Setting and Service Type

Across most cost components, the inclusion of the nursing process variables improved predictive performance, with variations depending on the care setting and model type (Table 2). For hospital care, the greatest increase was observed in the ensemble model, with R^2 increasing from 0.2161 to 0.2396 (+0.0235), while the improvements in the neural network and XGBoost models were similar (+0.0230 and +0.0223, respectively). For primary care, improvements were more moderate but consistent; the ensemble model increased from 0.4388 to 0.4442 (+0.0054), and comparable gains were observed for the neural network (+0.0050) and XGBoost (+0.0054). For emergency department visits, the predictive performance also increased, with that of the ensemble model increasing from 0.1431 to 0.1506 (+0.0075) and similar gains observed for XGBoost (+0.0074). For contracted care, improvements were more limited in magnitude but were observed across all models, with the ensemble model's performance increasing from 0.0389 to 0.0443 (+0.0054).

Outpatient consultations			
Neural network R^2	0.4568	0.4608	+0.0040
XGB R^2	0.4606	0.4652	+0.0046
Ensemble R^2	0.4598	0.4642	+0.0044
Emergency department visits			
Neural network R^2	0.1407	0.1473	+0.0066
XGB R^2	0.1434	0.1508	+0.0074
Ensemble R^2	0.1431	0.1506	+0.0075
Other cost components			
Pharmaceutical costs			
Neural network R^2	0.6565	0.6612	+0.0047
XGB R^2	0.6588	0.6631	+0.0043
Ensemble R^2	0.6584	0.6631	+0.0047

[a]XGB: extreme gradient boosting.

When analyzed by service type, outpatient consultations and emergency department visits showed the most consistent improvements. For outpatient consultations, the R^2 of the ensemble model increased from 0.4598 to 0.4642 (+0.0044), whereas for emergency department visits, it increased from 0.1431 to 0.1506 (+0.0075). For hospital admissions, the changes were minimal; the ensemble model R^2 increased slightly from 0.0641 to 0.0650 (+0.0009), whereas that of the neural network marginally decreased (−0.0006).

Predictive Models Using Latent Variables Derived From the Autoencoder

Finally, an autoencoder was applied to reduce the 789 nursing variables to 16 latent dimensions while preserving relevant data patterns. These compressed variables were incorporated with the sociodemographic, clinical, and AMG-related variables. With this combination, the models achieved R^2 values of 0.5013 for the neural network, 0.5062 for XGBoost, and 0.5052 for the ensemble model. Thus, dimensionality reduction markedly simplified the nursing feature space while yielding predictive performance that was broadly comparable to that of the models

XSL•FO
RenderX

using the larger nursing-variable set, but without a substantial performance improvement.

Discussion

Principal Findings

The integration of variables derived from nursing methodology into ML-based prediction of total and component-level health care costs resulted in small numerical improvements in total cost prediction, whereas changes observed across cost components were heterogeneous and, in many cases, of small magnitude. These results suggest that nursing information may contain an additional predictive signal, although the magnitude of this contribution was limited, thereby reflecting differences in care delivery structures and in the relationship between care processes and resource use. Accordingly, the balance between added model complexity and predictive benefit should be interpreted with caution, as the contribution of nursing information varies according to the care setting and service type considered.

To date, the predominant methodologies used in health care cost analysis have systematically excluded data related to nursing interventions and outcomes, despite evidence that nursing terminologies can improve both the quality and the efficiency of resource management [30]. Their standardization enables the documentation and quantification of nursing work and provides a holistic view of the patient that is not usually captured by traditional biomedical data. Recent studies have shown that incorporating nursing information into clinical databases facilitates a better understanding of the impact of nursing practice on patient outcomes [21] and contributes to improving patient safety [31], with a potential indirect effect on cost reduction.

However, the literature on the application of ML to nursing data has focused primarily on the development of intelligent clinical tools, such as virtual assistants, fall prediction models, and patient monitoring systems, rather than on economic outcomes [32]. In this context, the present study represents, to our knowledge, a novel approach by systematically integrating nursing process information into cost prediction models using ML techniques, thereby extending previous research in which the added economic value of nursing data has rarely been evaluated.

The use of ML algorithms has demonstrated usefulness in health care cost prediction by overcoming limitations inherent in traditional statistical models, such as data skewness and distributional bias [6,33]. In general, the variables most commonly used to predict health care expenditure are medical diagnoses and prescribed medications [2,34]. For example, in the study by Drewe-Boss et al [2], neural network–based models relied primarily on medical diagnoses coded according to the *International Classification of Diseases*, 10th Revision (ICD-10) and the Anatomical Therapeutic Chemical (ATC) classification system. In contrast, models built using ridge regression placed greater weight on Gebührenordnungspositionen codes, which are broadly comparable to the diagnosis-related groups used in Spain and other European countries.

Similarly, comorbidity may be a better predictor of pharmaceutical consumption and other health care products than clinical complexity, which encompasses psychological, social, and functional dimensions [35]. The findings of the present study are partially consistent with this pattern because the inclusion of nursing variables increased the predictive capacity for total health care costs, although the magnitude of this increase was modest. Nevertheless, given the limited magnitude of the observed improvement, its operational relevance for population risk adjustment or resource planning should be interpreted with caution.

Health care costs are complex and influenced by multiple factors. The incorporation of measures of well-being into prediction models has been shown to improve the estimation of future health care costs by 5.7% to 13% [36]. Another study revealed that each one-point increase in well-being indices was associated with a 1% reduction in health care expenditure [37]. Similarly, the inclusion of social determinants in predictive models has demonstrated additional benefits: in populations characterized by high levels of poverty, inequality, or lack of coverage, social determinants reduced cost underestimation and improved predictive performance by 3%, corresponding to approximately US $200 per person per year [18].

The integration of this type of data into ML models represents a promising avenue for improving the efficiency and sustainability of health care systems [38]. Along these lines, nursing data capture dimensions related to functional status, care needs, and human responses to health problems that are traditionally absent from cost models and could complement the social and clinical determinants commonly used.

In the analyses performed, pharmaceutical costs showed the highest predictive accuracy, with R^2 values increasing from 0.6584 to 0.6631 following the inclusion of nursing variables. This finding suggests that these variables may capture information related to therapeutic adherence, medication management, and educational processes, which are consistent with the role of nursing practice. Although the observed improvement was modest, its limited magnitude means that any interpretation regarding its practical usefulness should remain cautious. In contrast, in other areas, such as outpatient consultations or primary care, changes were small and, in some cases, showed a downward trend, indicating a limited effect of nursing variables in these specific settings. Overall, these patterns indicate that the contribution of nursing methodology is not uniform and may be more relevant in functions closely linked to clinical follow-up and pharmacological management.

In primary care, a setting in which nursing plays a central role, particularly in the management of chronic conditions, an improvement in predictive performance was also observed (R^2 increasing from 0.4388 to 0.4442). This result suggests that long-term care and continuous follow-up, areas with greater nursing involvement, may benefit more from the systematic incorporation of the nursing process into predictive models.

In contrast, the XGBoost models consistently showed better predictive performance than the neural networks in the present analysis, although the literature has reported mixed findings. For example, in a study on pharmaceutical cost prediction,

XSL•FO
RenderX

boosted tree–based models outperformed neural networks (area under the curve [AUC]=0.74) [39], whereas another study on hospital cost prediction reported better performance for neural networks (R^2=0.813) than for decision trees (R^2=0.713) [40]. Nevertheless, XGBoost is widely regarded as one of the most robust algorithms for tabular data and for scenarios with missing values [41]. The consistency of its performance in the present study further supports its suitability for complex health care data with multiple categorical and sparse variables, such as those derived from the nursing process.

One of the main uses of predictive models lies in identifying relevant features within large datasets and in understanding their contribution to outcome prediction. However, when the number of variables is high, the presence of irrelevant or redundant dimensions may adversely affect model performance by introducing noise and unnecessarily increasing complexity. In the present study, the modeling strategy was designed to assess the incremental predictive value of the nursing data block as a whole, rather than to determine the individual relevance of specific nursing diagnoses, outcomes, interventions, or functional patterns.

In this context, autoencoders have become established as effective tools for dimensionality reduction, redundancy elimination, and the generation of latent representations that preserve essential information [42]. In the present study, autoencoder implementation enabled the condensing of 789 nursing methodology variables into 16 latent variables. Although this reduction preserved relevant patterns and substantially simplified model complexity, it did not translate into a substantial improvement in predictive performance, indicating that dimensionality reduction alone was not sufficient to strengthen predictive performance in a meaningful way. Therefore, the autoencoder should be interpreted here as a strategy for representation simplification rather than as a predictive advantage. Future studies could explore which of these latent dimensions are most informative and whether they capture distinct patient profiles.

Among the most widely used health care management tools are risk-adjustment models such as ACGs, Diagnosis-Related Groups, and AMGs, which are extensively applied in Spain and other countries. These models are integrated into electronic health records with the aim of classifying morbidity, predicting hospital admissions or mortality, and estimating health care costs, thereby supporting efficient resource allocation and informing managerial decision-making. However, because they are largely based on linear statistical approaches, they present important limitations when applied in settings characterized by complex, nonlinear, and high-dimensional data, as is common in clinical information systems [15]. These limitations may result in the underestimation of actual health care costs and reduced predictive accuracy in scenarios of high care complexity.

In contrast, ML algorithms have been shown to outperform traditional models across several key metrics. For example, in mortality prediction, they achieve AUC values ranging from 0.92 to 0.94, compared with 0.91 for classical models, and in the prediction of hospital readmissions, performance improves from 0.69 to 0.75-0.76 [43]. In light of these findings, the present results suggest that combining ML algorithms with variables derived from the nursing process could increase the precision and practical use of current risk adjustment models, particularly in settings characterized by a high nursing workload.

Implications for Practice

The findings of the present study indicate that the systematic incorporation of variables derived from the nursing process into clinical information systems may contribute to improving the accuracy of health care cost prediction models and could enhance population stratification tools. Integrating these data may enable more accurate identification of patient groups with greater resource needs and facilitate the planning of more efficient, evidence-based interventions.

In addition, recognizing the predictive value of nursing documentation highlights its contribution to health care system management and underscores the importance of promoting structured, interoperable, and high-quality nursing records in clinical practice.

Strengths and Limitations

The present study has several limitations that should be considered when interpreting the findings. First, the observation period was limited to a single year, which restricts the ability to analyze long-term cost trajectories. Although previous studies have indicated that predictive performance improves with longer follow-up periods [2,44], the use of a large population-based cohort (N=1,691,075) provides a robust foundation and reduces the risk of overfitting, thereby strengthening the external validity of the analysis.

Second, comparability with other studies is limited because of the heterogeneity in the algorithms, validation strategies, and performance metrics reported in the literature. In addition, no studies have been identified that have systematically integrated nursing process variables into health care cost prediction models, which hinders direct comparison but also highlights the innovative nature of this work.

Another limitation relates to dimensionality reduction using autoencoders. Although this approach enabled the synthesis of 789 nursing variables into 16 latent components, the clinical interpretability of these components was lower, and no substantial improvement in predictive performance was observed. Nevertheless, these latent representations offer opportunities for future research aimed at identifying patient profiles and patterns associated with resource use.

Finally, the rapid evolution of AI techniques means that some approaches may become outdated over time. However, the methods applied represent well-established standards in ML and are appropriate for the stated objectives. Replicating the present study in other health care systems would help strengthen the generalizability of the findings and broaden their applicability.

Conclusions

The incorporation of variables derived from the nursing process into ML-based health care cost prediction models was associated

XSL•FO
RenderX

with small incremental improvements in the explanatory capacity for total health care costs, whereas effects observed across cost components were heterogeneous and of smaller magnitude. These findings suggest that structured nursing information may complement the sociodemographic, clinical, and morbidity-related variables commonly used in health care expenditure estimation.

The results highlight the relevance of moving toward the integration of nursing process information into population-stratification systems and risk-adjustment models, which are key tools for health care planning and efficient resource allocation. The inclusion of dimensions related to functional status, care needs, and human responses broadens the traditional perspective based on clinical and administrative data, thereby supporting more comprehensive approaches to cost prediction.

The potential of ML to improve the estimation of health care resource use should not be limited exclusively to conventional biomedical predictors. The incorporation of structured information derived from nursing practice may enhance the understanding of the determinants of health care costs and support the development of more holistic, person-centered predictive models aligned with contemporary approaches to integrated care.

Abstract

Background: Gaps in knowledge, inhalation skills, and adherence continue to hinder effective chronic obstructive pulmonary disease (COPD) management.

Objective: The study was conducted to describe the status of COPD-related knowledge, practical skills for inhalation and breathing exercises, and treatment adherence among patients with COPD and to identify the relationships between these variables.

Methods: A cross-sectional study was conducted among 420 outpatients with COPD. Data were collected in 2 rounds, including interviews to assess patients' knowledge and treatment adherence and checklist-based observations of patients' practical skills. Multivariable logistic regression analysis was used to evaluate the associations between knowledge and practical skills and the status of treatment adherence.

Results: A total of 420 outpatients with COPD were included; 331 (78.8%) participants had inadequate COPD-related knowledge, 268 (63.8%) demonstrated adequate practical skills, and 155 (36.9%) achieved overall treatment adherence. In multivariable logistic regression, higher knowledge scores were associated with better treatment adherence (adjusted odds ratio [aOR] 1.20, 95% CI 1.06 - 1.31; *P*=.001). Participants who correctly performed inhaler-use techniques were more likely to be adherent than those with incorrect technique (aOR 3.10, 95% CI 2.10 - 4.70; *P*=.001). Likewise, adequate breathing-exercise skills were associated with higher adherence (aOR 1.70, 95% CI 1.08 - 2.71; *P*=.02).

Conclusions: Higher COPD-related knowledge and better practical skills in inhaler use and breathing exercises were associated with better treatment adherence among outpatients with COPD. Because of the cross-sectional design, these findings indicate associations rather than causal relationships. These observed associations may help inform future intervention studies evaluating patient education and skill-based training, although their effectiveness should be confirmed in longitudinal or interventional studies.

KEYWORDS

breathing exercises; chronic obstructive pulmonary disease; COPD; inhaler use; knowledge; treatment adherence

Introduction

Chronic obstructive pulmonary disease (COPD) is becoming a major global health challenge. According to the 2024 report of the Global Initiative for Chronic Obstructive Lung Disease (GOLD), there were about 3 million deaths globally each year, and by 2060, the world is estimated to have about 5.4 million deaths related to COPD [1]. In Vietnam, the prevalence of COPD among people aged 40 years and older is 4.2%, and approximately 1.3 million people with COPD currently require diagnosis and treatment [2]. Because of the prevalence,

XSL•FO
RenderX

prolonged progression, high treatment costs, and complex complications of COPD, this disease places a substantial burden on patients and health care systems worldwide and is associated with high morbidity and mortality [1].

Poor treatment adherence in COPD may be influenced by multiple factors, including inadequate disease-related knowledge, limited confidence in treatment, incorrect inhaler technique, and insufficient understanding of symptom management and breathing exercises [3]. These barriers may contribute to exacerbations, prolonged hospitalization, and poorer quality of life [1]. One of the major challenges in COPD management is ensuring that patients receive adequate education and support to understand and implement recommended self-management practices. Teaching and using an action plan in the event of worsening respiratory symptoms have been shown to reduce severity and shorten recovery time [4,5]. For patients to participate effectively in self-management programs, they must understand their disease as well as how to use medications and perform breathing exercises properly at home.

Treatment adherence is critical to the effective management of COPD and is key to addressing the growing burden of the disease [4]. For patients with COPD in the stable stage, adherence to medication and respiratory rehabilitation through the practice of breathing exercises are key to managing and alleviating symptoms, improving lung function, respiratory muscle strength, and exercise capacity, as well as reducing dyspnea and improving the quality of life [1]. However, many studies have shown that long-term adherence to chronic disease treatment is low, and it is estimated that only 50% of patients comply with treatment [6]. In addition, after the COVID-19 pandemic was brought under control in Vietnam, bed occupancy in respiratory departments of healthcare facilities has increased, coinciding with a large number of hospitalized patients with COPD exacerbations. One of the main reasons for this situation is that patients do not adhere to treatment.

To date, evidence regarding the relationship between treatment adherence, disease-related knowledge, and practical self-management skills among outpatients with COPD in Vietnam remains limited. This study aimed to assess COPD-related knowledge, practical skills in inhaler use and breathing exercises, and treatment adherence among outpatients with COPD and to examine the associations between knowledge, practical skills, and treatment adherence.

Methods

Study Design and Settings

A cross-sectional study was conducted among outpatients with COPD who were recruited from 3 hospitals, including Hospital C, Da Nang Hospital, and Da Nang Hospital for Lung Diseases, from April 2021 to August 2022 in Vietnam. This manuscript was prepared in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) reporting guideline for cross-sectional studies.

Participants and Sampling

The sample size was calculated based on the following formula:

$$n=(Z1-\alpha 2)2\times P\times(1-P)d2$$

Where $Z1-\alpha/2$ is the corresponding value at the selected confidence level (equal to 1.96 if the confidence level is 95%), P is the treatment adherence rate (50%) [7], and d is the absolute error of 5%.

On the basis of the formula, the required sample size for the study was 384. In addition, the research team estimated that about 10% of participants would withdraw after signing the consent form or would not complete the survey form; therefore, the minimum sample size was set at 420. All participants were recruited using convenience sampling.

The inclusion criteria were patients diagnosed with COPD; receiving home drug therapy with inhaled medications; able to speak, read, and understand Vietnamese; and willing to participate in the study.

The exclusion criteria were patients with a history of bronchial asthma, allergic rhinitis, lung surgery, or other acute respiratory diseases; experiencing COPD exacerbations or exacerbations of comorbidities or who had experienced medication changes within the previous 3 months; or with mental disorders or other serious illnesses.

On the basis of outpatient clinic records from the 3 participating hospitals, a list of 653 patients with a physician-confirmed diagnosis of COPD who attended follow-up outpatient visits and were receiving inhaled maintenance treatment between April 2021 and August 2022 was compiled. The research team contacted these patients by telephone, explained the purpose and importance of the study, and invited them to participate. A total of 497 patients agreed to participate. Reasons for nonparticipation mainly included advanced age, poor health status, living far from the hospital, or lack of family support for transportation. After applying the inclusion and exclusion criteria at the time of data collection, 420 participants were enrolled in the final analysis.

Measures

The questionnaire included 4 parts.

Part 1: Sociodemographic and Clinical Characteristics

The demographic questionnaire designed by the research team comprised 7 items (age, sex, education level, employment, years since diagnosis, smoking, and disease severity). Disease severity was assessed using the modified Medical Research Council (mMRC) questionnaire and the COPD Assessment Test (CAT). Both instruments have been translated into Vietnamese and officially published by the Ministry of Health of Vietnam and have been widely used in COPD research in Vietnam [8]. Patients were classified as having mild disease when mMRC scores were 0 to 1 and CAT scores were <10 and were classified as severe when mMRC scores were ≥2 and CAT scores were ≥10.

Part 2: Knowledge About COPD

Knowledge about COPD was measured using the Chronic Obstructive Pulmonary Disease Knowledge Questionnaire developed by Maples et al [9]. This scale consisted of 13 questions; each item was scored as 1 (correct) or 0 (incorrect

XSL•FO
RenderX

or unknown). Overall, patients were considered to have adequate knowledge if their total score was ≥10, whereas a total score of <10 indicated inadequate disease knowledge [9]. The Vietnamese version of the scale has been evaluated in 90 people with COPD, and the results showed good content validity and internal consistency (Kuder-Richardson formula 20 was 0.883 and 0.866 before and after the test, respectively). The test-retest reliability after 4 weeks was high (r=0.996; P<.001) [10].

Part 3: Practical Skills Assessment

Patients' practical skills were assessed using 2 observational checklists developed based on the 2020 Vietnamese Ministry of Health guideline for the diagnosis and treatment of COPD [11]. These assessments covered 2 domains: inhaler-use technique and breathing-exercise technique.

The inhaler-use checklist assessed patients' ability to use metered-dose inhalers (MDIs) with 6 steps and a Turbuhaler in 6 steps. For each step, patients received 2 points for correct performance, 1 point for incorrect performance, and 0 points for failure. According to Ngo et al [8], patients were classified as having "passed" if they performed all steps correctly, and as having "failed" if at least 1 step was performed incorrectly or not performed.

The checklist for breathing exercises included pursed-lip breathing (4 steps) and diaphragmatic breathing (4 steps). For each step performed correctly, patients received 2 points, while incorrect performance received 1 point, and wrong or failed steps received 0 points. The overall assessment was classified as "passed" if the patient performed all steps of the checklist correctly and fully, and "failed" when at least one step was wrong or not performed [12].

Part 4: Treatment Adherence

Treatment adherence was defined as the extent to which patients followed health care providers' recommendations regarding 2 main components of COPD treatment: inhaled medication use and breathing exercises.

Adherence to inhaled medication was assessed using the 10-item Test of Adherence to Inhalers (TAI-10), developed by Plaza et al [13]. Each item was rated on a 5-point Likert scale ranging from 1 ("worst adherence") to 5 ("best adherence"), yielding a total score from 10 to 50. Patients with a total score of 46 to 50 were classified as adherent to inhaled medication, whereas those with a score of ≤45 were classified as nonadherent. The TAI-10 has demonstrated good reliability in previous studies, with a Cronbach α of 0.871 and a test-retest reliability coefficient of 0.832 (P<.01) [14].

Adherence to breathing exercises was assessed based on both the correctness of breathing-exercise performance and the maintenance of daily practice frequency according to recommendations from the GOLD and the Vietnamese Ministry of Health COPD guideline. A checklist was used to evaluate whether patients correctly performed the prescribed breathing exercises. Patients were classified as adherent to breathing exercises only if they met both of the following criteria: (1) correctly performed all required steps of the breathing exercises and (2) maintained daily practice for at least 10 to 15 minutes, with a gradual increase according to their physical capacity. Patients who performed the breathing exercises correctly but did not maintain daily practice or who practiced daily but did not perform the exercises correctly were classified as nonadherent to breathing exercises. The assessment criteria for breathing-exercise adherence were developed based on guideline recommendations and expert consensus from 5 respiratory physicians and nurses at Hospital C, Da Nang.

Overall treatment adherence was defined as adherence to both inhaled medication and breathing exercises. Patients were classified as adherent overall only if they were adherent to both components; those who were adherent to only one component or to neither component were classified as nonadherent overall. The complete set of questionnaire items is presented in Multimedia Appendix 1.

Statistical Analysis

The study used SPSS (version 23.0; IBM Corp) for data analysis. Descriptive statistics were used to describe variables. Univariate analysis (chi-square test and independent-sample 2-tailed t test) was performed to examine the association between independent variables and treatment adherence. Variables with P<.05 (or P<.20 where appropriate) in univariate analysis were considered for inclusion in the multivariable model. Multivariable logistic regression analysis was then conducted to identify independent factors associated with treatment adherence, including demographic characteristics, clinical variables, knowledge, and practical skills. Adjusted odds ratios (aORs) with 95% CIs were reported. P<.05 was considered statistically significant.

Ethical Considerations

The Protocol Approval Committee and the Medical Ethics Committee of Nam Dinh University of Nursing approved the study (1681/GCN-HDDD) on August 2, 2021. Participants provided written informed consent before participation.

Results

General Characteristics and Clinical Features of Patients With COPD

Among 420 participants, most were male (n=335, 79.8%). The mean age was 59.5 (SD 8.2) years. Most participants had a post–high school education level (n=346, 82.4%). Regarding employment status, 202 (48.1%) participants were retired, whereas only 33 (7.8%) were engaged in free trade. The mean time since diagnosis was 11.39 (SD 5.46) years, and 51.4% (n=216) of the participants were smokers (Table 1).

[b]CAT: COPD Assessment Test.

Patients' Knowledge About COPD

Among 420 participants, 331 (78.8%) had inadequate knowledge about COPD, whereas 89 (21.2%) had adequate knowledge. Item-level analysis showed that knowledge gaps were mainly related to smoking cessation and medication use (Table 2). Specifically, the items with the lowest correct response rates were "Quitting smoking will prevent the disease from getting worse" (n=53, 12.6%) and "Medications prevent the disease from getting worse" (n=60, 14.3%). The item with the highest correct response rate was "Shortness of breath is a symptom of COPD" (n=375, 89.2%; Multimedia Appendix 2).

Table . Patient's knowledge, practice skills, and treatment adherence about chronic obstructive pulmonary disease (COPD; n=420).

Practical Skills of Patients With COPD

Overall, of 420 participants, 152 (36.2%) failed the overall practical skills assessment, whereas 268 (63.8%) passed (Table 2). For the MDI technique, 112 (26.7%) participants failed, with the most common error being failure to exhale slowly before inhalation (77/112, 68.8%). For the Turbuhaler technique, 40 (9.5%) participants failed, and incorrect inhalation technique was the most frequent error (28/40, 70%).

Regarding breathing-exercise skills, 278 (66.2%) participants correctly performed both breathing exercises during the practical skill assessment, whereas 142 (33.8%) did not (Multimedia Appendix 3).

Treatment Adherence of Patients With COPD

Overall treatment adherence was observed in 155 (36.9%) of 420 participants, whereas 265 (63.1%) were classified as nonadherent (Table 2). Adherence to inhaled medication was observed in 234 (55.7%) participants, and adherence to breathing exercises was observed in 265 (63.1%) participants (Multimedia Appendix 4).

Factors Associated With Treatment Adherence of Patients With COPD

In univariate analysis, disease severity, smoking status, knowledge scores, inhaler-use skills, and breathing-exercise skills were significantly associated with treatment adherence (P<.05). Age, sex, education level, employment status, and duration of illness were not significantly associated with treatment adherence. Variables with P<.20 in univariate analysis were entered into the multivariable logistic regression model (Multimedia Appendix 5).

Knowledge scores were significantly associated with treatment adherence (adjusted odds ratio [aOR] 1.20, 95% CI 1.06 - 1.31; P=.002). Participants who passed the inhaler-use skill assessment had higher odds of overall treatment adherence than those who failed (aOR 3.10, 95% CI 2.01 - 4.75; P=.001). Similarly, participants who passed the breathing-exercise skill assessment had higher odds of overall treatment adherence than those who failed (aOR 1.70, 95% CI 1.08 - 2.71; P=.02; Table 3). Among these factors, correct inhaler-use technique showed the strongest association with treatment adherence.

Table . Factors associated with treatment adherence in the multivariable logistic regression model[a].

Factors	B	aOR[b] (95% CI)	*P* value
Age (years)	−0.02	0.98 (0.95 - 1.01)	.14
Sex

[c]Not applicable.

Discussion

Principal Findings

This study found that COPD-related knowledge, observed practical skills, and treatment adherence among outpatients with COPD were generally suboptimal. Nearly 4 in 5 participants lacked adequate COPD-related knowledge, more than one-third demonstrated poor practical skills, and only 36.9% (155/420) achieved overall treatment adherence. In addition, better knowledge and adequate inhaler-use and breathing-exercise

XSL•FO
RenderX

skills were significantly associated with higher treatment adherence.

COPD has become a major cause of morbidity and mortality worldwide. Currently, COPD cannot be completely cured, but early treatment and adherence to treatment recommendations can reduce symptoms, slow the progression of lung damage, and improve patients' quality of life [15].

The study found that 78.8% (331/420) of patients with COPD lacked knowledge about the disease; this proportion was higher than that reported by Yang et al [16]. In addition, when comparing the correct response rates, our study and the study by Yang et al [16] showed similar patterns regarding the highest and lowest correct response rates. Specifically, the highest correct response rate was for "shortness of breath as a symptom" at 89.2% (375/420) in our study and 77.7% in the study by Yang et al [16]. This similarity can be explained by dyspnea being one of the most typical and frequent symptoms of COPD. Most people with COPD experience dyspnea when they are physically active, even in the early stages, and as the disease progresses, this problem gradually increases in intensity and severity and may occur even at rest. Two items with the lowest correct response rates were "Medications to prevent the disease from getting worse" with a correct response rate of only 14.3% (60/420) in our study compared with 10.7% in the study by Yang et al [16] and "Quitting smoking will prevent the disease from getting worse" with 12.6% (53/420) and 11.8%, respectively [16]. These knowledge assessments were related to the progression of COPD. Although most patients with COPD know that regular medication use and smoking cessation are beneficial for disease management, many do not seem to realize that with COPD, lung function cannot be fully restored [16,17]. Currently, there are no drugs or methods that can completely reverse the decline in lung function in people with COPD [17]. These findings highlight areas in which patients demonstrated substantial knowledge gaps. Educational strategies addressing these topics could be evaluated in future intervention studies.

Our study also found that 63.8% (268/420) of patients demonstrated adequate inhaler-use skills, which was higher than some studies conducted in Italy (50%) and in Korea (46.7%) but lower than that reported in a study in Pakistan (93.7%) [18-20]. Among inhaled bronchodilators used by patients, the most common errors were related to the use of the MDI and Turbuhaler, with error rates of 26.7% and 9.5%, respectively. Compared with previous studies, these rates were lower than those reported in the study in Pakistan (60% and 41%, respectively) [20] and the study by Molimard et al [21] (46.9% and 32.1%, respectively). In addition, when assessing the errors that patients often made when using the MDI and Turbuhaler, our study showed that the highest rate was for "Haven't exhaled very slowly yet," at 68.8% (77/112) for the MDI and 50% (20/40) for the Turbuhaler. This rate was higher than that reported by Molimard et al [21] in a study of 2935 patients with COPD hospitalized with acute exacerbations.

Most patients practiced both breathing exercises adequately (278/420, 66.2%); almost all patients passed the skills assessment when performing pursed-lip breathing (346/420, 82.4%), while diaphragm breathing exercises were still low, with 56%. This may be because diaphragmatic breathing involves more complex steps than pursed-lip breathing. These findings suggest that breathing exercises remain an important area for patient education; however, whether educational interventions improve adherence should be confirmed in future interventional studies. Additionally, our results were similar to previous research [22,23].

Treatment adherence in this study was defined as adherence to 2 key components of the prescribed COPD treatment regimen: inhaled medication use and breathing exercises. The overall treatment adherence rate was low, with only 36.9% (155/420) of participants meeting both criteria. One possible explanation is that many previous studies assessed adherence primarily in terms of medication use alone, whereas our study applied a broader and more stringent definition that required adherence to both inhaled medication and breathing exercises. This composite approach may partly explain the lower overall adherence rate observed in our sample. In addition, the study was conducted during the COVID-19 pandemic period, when limited access to health care services, reduced follow-up visits, and fear of infection may also have negatively affected treatment adherence. When inhaled medication adherence was considered separately, 55.7% (234/420) of patients were classified as adherent according to the TAI-10. This finding differs from those reported in previous studies. A study in Greece reported a high rate of nonadherence to inhaled medication (74.1%) [24], whereas studies from several European, Latin American, and Asian countries reported lower nonadherence rates [25-27]. These differences may be related to variations in study populations, health care systems, adherence assessment tools, and the operational definitions of adherence used across studies. The inclusion of breathing exercises in the definition of overall treatment adherence was based on the clinical management of COPD, which involves not only pharmacological treatment but also nonpharmacological interventions. In the present study, adherence to breathing exercises was defined not merely by correct technique but by both correct performance and maintenance of daily practice according to the prescribed recommendations. These findings suggest that inhaler technique and breathing-exercise skills may represent potential targets for future nursing interventions. However, the present cross-sectional study cannot determine whether such interventions improve treatment adherence.

In addition, higher COPD knowledge was significantly associated with greater odds of treatment adherence, suggesting that patients who better understand their disease and its management may be more likely to follow prescribed treatment recommendations. This finding is consistent with previous studies [28]. Participants who passed the inhaler-use skill assessment had 3.1-fold greater odds of overall treatment adherence than those who failed, representing the strongest association observed in the present study and consistent with previous findings [29]. Similarly, participants who passed the breathing-exercise skill assessment had 1.7 times higher odds of overall treatment adherence than those who failed, which is also in line with earlier research [16]. These findings should not be interpreted as meaning that practical skills are equivalent to adherence. Rather, they suggest that correct performance of

XSL•FO
RenderX

inhaler-use techniques and breathing exercises may reflect a patient's ability to understand, retain, and implement treatment instructions, which in turn may support better adherence behavior. In other words, practical skills in this study should be considered correlates of treatment adherence rather than direct measures of adherence itself. Because this was a cross-sectional study, the temporal direction of these associations cannot be determined, and causal relationships cannot be inferred.

Although knowledge and practical skills were significantly associated with treatment adherence in the multivariable model, these associations should be interpreted with caution. In the context of COPD management in Vietnam, adherence behavior is likely influenced not only by patients' knowledge and self-management skills but also by broader contextual factors such as medication affordability, health insurance coverage, family support, and the quality of patient–health care provider communication. These factors may affect a patient's ability to obtain medications, attend follow-up visits, understand treatment instructions, and maintain regular breathing exercises and may therefore be closely intertwined with both treatment adherence and the measured knowledge and skill variables. Because these contextual variables were not collected and could not be included in the regression model, residual confounding and omitted variable bias cannot be excluded. As a result, the independent contributions of COPD knowledge, inhaler-use skills, and breathing-exercise skills may have been overestimated to some extent. Therefore, the present findings should be interpreted as associations within the measured model rather than as evidence of fully independent causal effects.

Strengths and Limitations

Treatment adherence in this study was assessed using a combination of methods, including the self-reported TAI-10 for inhaled medication adherence and a structured assessment of breathing-exercise adherence. In addition, patients' inhaler-use and breathing-exercise skills were evaluated by direct observation using standardized checklists, which provided complementary information on practical performance.

However, this study has several limitations. First, data collection was conducted shortly after the COVID-19 pandemic was brought under control in Da Nang City, which created challenges in accessing and recruiting the target population. Although the final sample included 420 participants from 3 hospitals, caution is still needed when interpreting the representativeness of the findings. Second, treatment adherence in COPD is multidimensional and may include not only adherence to inhaled medications and breathing exercises but also smoking cessation, dietary recommendations, physical activity, and other self-management behaviors. Due to resource constraints and study feasibility, the present study focused only on adherence to inhaled medications and breathing exercises. Therefore, the findings may not fully reflect overall adherence to all recommended COPD management behaviors. Third, the study did not assess the quality of physician-patient communication or patient–health care provider relationships, which may substantially influence patients' understanding of treatment, motivation, and adherence behaviors. Future studies should incorporate communication-related factors to provide a more comprehensive explanation of treatment adherence among patients with COPD. Fourth, some invited patients declined participation because of older age, frailty, transportation difficulties, or limited family support. In addition, patients who had experienced COPD exacerbations, exacerbations of comorbidities, or medication changes within the previous 3 months were excluded from the study. These factors may have introduced selection bias toward a relatively more stable and healthier subgroup of patients and may therefore have led to an overestimation of treatment adherence compared with the broader COPD population receiving follow-up care. Fifth, the study did not specify a minimum duration since COPD diagnosis or initiation of inhaled treatment. As a result, participants may have differed in their level of experience with disease management, inhaler use, and breathing exercises, which could have affected the homogeneity of the sample and should be considered when interpreting the findings. Finally, because this was a cross-sectional study, temporal relationships between COPD knowledge, practical skills, and treatment adherence could not be established. Therefore, causal inferences cannot be drawn. Longitudinal cohort studies and intervention trials are required to determine whether improving knowledge and practical skills leads to better treatment adherence.

Conclusions

Higher COPD-related knowledge and better practical skills in inhaler use and breathing exercises were associated with better treatment adherence among outpatients with COPD. Because this study used a cross-sectional design, these findings demonstrate associations rather than causal relationships. The observed associations indicate that patient education and skill-based training warrant further investigation as potential nursing interventions; however, their effectiveness in improving treatment adherence should be confirmed in longitudinal cohort studies and randomized controlled trials before causal conclusions are drawn.

Abstract

Background: Leadership development programs in health care often fail due to their lack of adaptability to the schedules of busy clinicians. This study addressed the need for scalable, flexible programs tailored to nurse leaders.

Objective: This study evaluated the acceptability, appropriateness, and feasibility of the Relational Playbook, an evidence-based leadership development program developed in the Veterans Health Administration delivered through the Whistle Systems employee recognition web application and mobile app.

Methods: A 1-year, single-team pilot was deployed using descriptive survey data and qualitative interview analysis. The Relational Playbook's educational content and interventions were hosted on the Whistle platform, which integrates behavioral science and gamification strategies. Content was delivered weekly via app-based nudge notifications and email. Engagement metrics included activity completion rates. User experience data were collected through weekly reflection surveys (with Likert-scale responses and open-text options); monthly check-ins; and a postimplementation acceptability, appropriateness, and feasibility survey and interview. Descriptive statistics summarized engagement levels and trends, and qualitative data were analyzed using content analysis to identify recurring concepts. Quantitative and qualitative data were analyzed sequentially for comprehensive insights.

Results: The section chief and 4 practicing cardiology nurse practitioners from a large academic medical center participated. The nurse practitioner section chief deemed the Whistle platform an acceptable, appropriate, and feasible technology for delivering the Relational Playbook content. They valued the weekly nudges, microlearning content, and flexibility of the web application and mobile app. The Relational Playbook content supported their personal growth and fostered positive shifts in attitudes toward work.

Conclusions: Delivering leadership development content through the Whistle platform is an acceptable approach to support the growth and well-being of busy nurse leaders. The small sample and absence of a comparison group limit generalizability.

leadership; nursing; mobile app; development; workforce

Introduction

The well-being of nurse leaders and the nursing workforce is an urgent concern worsened by the COVID-19 pandemic, increasing patient complexity, evolving hospital systems, and high workloads [1]. Nurse leaders play a pivotal role in improving nurse well-being, patient care, and clinical outcomes by managing frontline clinical staff [2]. However, leadership is a challenging role that requires skills to foster interdisciplinary teamwork, continuous learning, and high reliability. Most nurse leadership training occurs through face-to-face didactic education or on-the-job training that falls short of true leadership development [3]. Digital leadership programs are available; however, most lack scientific rigor and impact evaluation [4].

XSL•FO
RenderX

With many nurse leaders nearing retirement, developing the next generation is essential to sustaining the profession and ensuring high-quality care [5].

The Relational Playbook is an innovative leadership development program grounded in adult learning principles, including experiential learning [6] and situated learning theories [7]. The Relational Playbook is designed to equip frontline clinical leaders with the skills to foster a culture of learning and high reliability within clinical teams. The Relational Playbook integrates evidence-based concepts and practices from positive psychology, team science, servant leadership, the Veterans Health Administration (VHA) Whole Health model, and clinical team training [8-10]. The Relational Playbook's key innovation lies in bringing these principles together into a single, cohesive program tailored specifically for frontline health care leaders. These principles are presented in an e-book with five chapters on (1) creating a positive culture, (2) teamwork, (3) leading teams, (4) creating joy in work, and (5) communication and high reliability. The Relational Playbook contains brief asynchronous learning modules, 11 kick-off interventions, and 39 additional evidence-based interventions. Table 1 provides more details on the Relational Playbook chapters, their resource topics, and their kick-off interventions. Frontline leaders complete weekly self-directed education and then select and implement specific Relational Playbook interventions into existing meetings or trainings. Each chapter builds on the previous one and results in the development of supportive learning environments.

Table . Relational Playbook chapters, modules, and kick-off interventions.

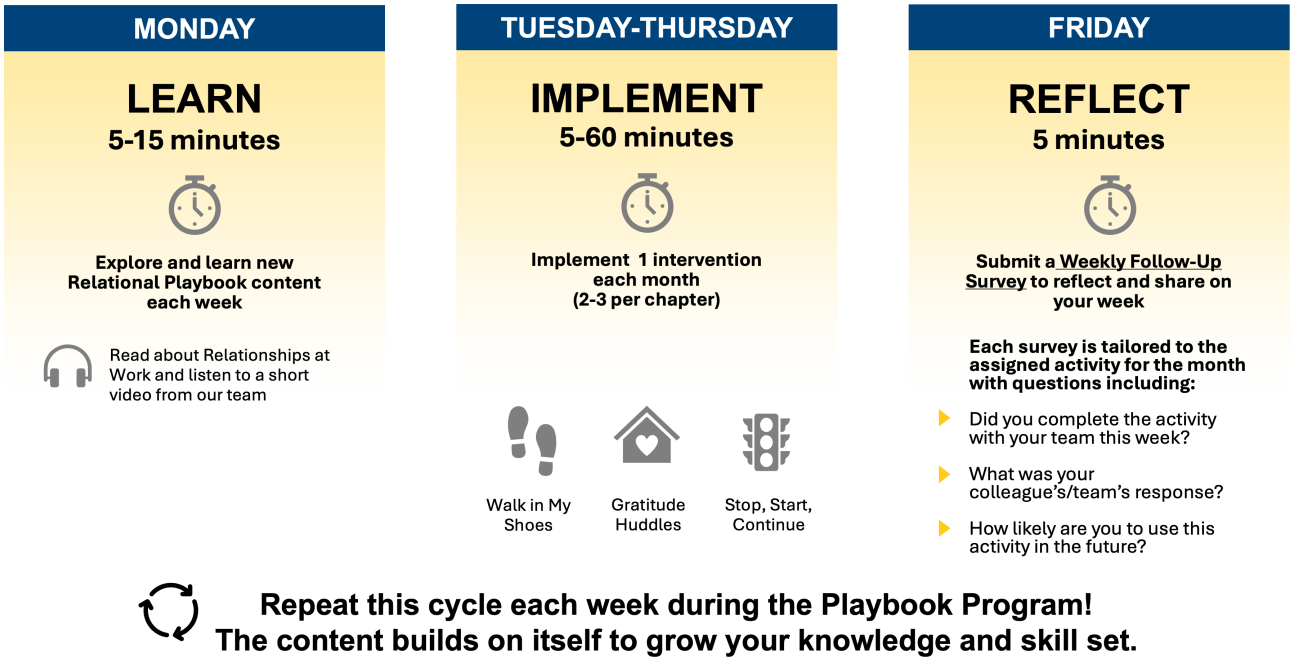
Relational Playbook chapter	Resource topics	Kick-off interventions
Chapter 1: Creating a Positive Culture	• Positive culture • Assessing team well-being • Appreciative inquiry	• "Three Good Things" practice [11] • Appreciative inquiry questions [12]
Chapter 2: Teamwork	• Building a team • Relationships at work • Difficult relationships at work • Hiring for high-performing teams	• "Walk in My Shoes" exercise [13] • Ice breaker questions [13]
Chapter 3: Leading Teams	• Wellness-centered leadership • Servant leadership • Essential leadership skills	• "Stop, Start, Continue" method [13] • "Situation-Behavior-Impact" feedback [14]
Chapter 4: Creating Joy in Work	• Burnout • Joy and happiness • Gratitude	• Understanding what matters [15] • "Was It Worth It?" method [16] • Gratitude huddle [17]
Chapter 5: Communication and High Reliability	• Effective communication • High-reliability practices	• Start-of-day huddles [18] • Debriefs [18]

Pilot research with the Relational Playbook has suggested improvements in employee engagement and retention while reducing burnout and turnover, which are critical workforce challenges [8]. The Relational Playbook aligns with multiple priority areas in health care, including the shift toward learning health systems to improve patient safety. In 2022, the Relational Playbook was registered as an invention with the VHA Technology Transfer Program (VHA ID 2022-474) to foster partnerships with external digital technology innovators and leverage emerging technology to expand and scale the program.

The Relational Playbook team collaborated with Whistle Systems, a company specializing in digital programs and trainings to sustain employee behavior change and improve workplace culture. Leveraging a mobile-first design, the Whistle platform integrates evidence-based strategies such as microlearning, gamification, and strategic nudges to optimize user engagement and adherence [19]. The platform delivers real-time feedback through notifications, on-demand resources, and a user-centric interface to enhance accessibility. Whistle has shown measurable success in improving employee engagement and reducing turnover across sectors, including aviation, finance, and construction [20]. The partnership aimed to adapt Relational Playbook content to the Whistle platform and assess whether this innovative technology is an acceptable, appropriate, and feasible tool for delivering the Relational Playbook to nurse leaders.

Methods

Overview



We conducted a 1-year, single-team feasibility study of the Relational Playbook delivered on the Whistle platform within a real-world clinical setting using descriptive survey data and qualitative interview analysis. A cardiology nurse practitioner (NP) team (n=5) at a large academic medical center volunteered to pilot the Relational Playbook on Whistle driven by an interest in leadership development training to improve team dynamics. The NP section chief was the primary participant, and their team members were invited to engage with the platform to enhance team understanding and participation. To maintain participant confidentiality, detailed demographic information was not reported. The inclusion criterion was a formal supervisory role in the department. Participation was voluntary and considered part of the employees' work.

XSL•FO
RenderX

The Relational Playbook and Whistle team established a cooperative research and development agreement enabling collaboration between the VHA and private companies. The first author adapted the Relational Playbook content for delivery on the Whistle platform with input from the Relational Playbook developers (HMG and BC) and Whistle engineers. The educational content was reformatted into a microlearning flash card model incorporating short text, colored images, videos, and kick-off interventions (Multimedia Appendix 1). The Whistle-enabled Relational Playbook used multiple behavioral science mechanisms, including celebratory feedback (confetti) to trigger dopaminergic reward responses, progress indicators (completion bars) to leverage the goal gradient effect, microlearning modules to reduce cognitive load and enhance perceived task simplicity, and strategic nudges to serve as action triggers and mitigate decision inertia. The Whistle web platform hosted the content, with accessible iPhone and Android mobile apps.

The Relational Playbook on Whistle begins with participants completing the 13-item Learning Environment Assessment Tool (Multimedia Appendix 2), an abbreviated version of the validated 64-item Learning Environment Survey [10,21]. The Learning Environment Assessment Tool evaluates key aspects of supportive learning environments through statements such as "The cardiology team demonstrates trust and mutual respect with each other," "The cardiology team is comfortable asking for help and feedback from others," and "The cardiology team can control their own practice and regularly participate in decisions about their work." Each item is rated on a 3-point scale (1="rarely," 2="sometimes," and 3="almost always"). Responses are automatically summed in Qualtrics (Qualtrics International Inc) and ranked from lowest to highest. Using these data, the research team assigned initial (lowest ranking) and subsequent chapters to the participants in order. The Relational Playbook consists of 5 chapters, each delivered over a 2-month interval across 1 year (Figure 1). Participants receive weekly email and app notifications ("nudges") linking to flash card–based learning modules. Each module concludes with a brief comprehensive quiz and celebratory feedback to reinforce engagement. Modules end with details about the next chapter's kick-off intervention to implement.

Figure 1. The Relational Playbook program weekly activities. This figure shows what a week in the Relational Playbook looks like for a cardiology nurse practitioner team. On Monday, they are instructed to take 5 to 15 minutes and learn new content by completing learning modules and watching short videos. The rest of the week, they implement their learnings and activities through 1 intervention each week, such as "Walk in My Shoes" or "gratitude huddles." At the end of the week, they submit a weekly follow-up survey that is tailored to the assigned activity for the month to see whether they progressed with the activity and their team's response.

The evaluation data were collected through surveys and interviews from the NP section chief (eg, primary participant) to measure implementation, engagement, and adoption outcomes. Primary implementation outcomes were the acceptability, appropriateness, and feasibility of the Relational Playbook on Whistle assessed using the Acceptability of Intervention Measure, Feasibility of Intervention Measure, and Intervention Appropriateness Measure [22] (Multimedia Appendix 3). These surveys assess the acceptability, appropriateness, and feasibility of the Relational Playbook on Whistle through statements such as "The Relational Playbook on Whistle meets my approval," "The Relational Playbook on Whistle seems suitable," and "The Relational Playbook on Whistle seems implementable." Each item is rated on a 5-point scale (1="completely disagree"; 5="completely agree") and analyzed using mean scores [22]. The secondary outcomes of engagement and adoption were assessed using all participant platform visit data and survey responses (n=5), supplemented by a follow-up interview with the NP section chief to contextualize the findings. Whistle's reporting tools were used to track platform visits, module completions, survey completions, and responses.

Quantitative data, including platform use and survey responses, were summarized both by chapter and for the Relational

XSL•FO
RenderX

Playbook overall. Chapter and Playbook completion rates were calculated as the percentage of completed modules relative to the total number of modules using Microsoft Excel. Platform visit data were reviewed to confirm that all participants accessed the Relational Playbook content on Whistle at least once. For qualitative data, we used a rapid qualitative matrix approach [21]. Two team members (BC and MD) met to discuss data and reach consensus on the concepts; given the informal nature and small sample (n=1), all data were analyzed instead of stopping at a point of saturation. The initial matrix summary was developed by 1 team member using identified concepts and illustrative quotes from the data. A second team member independently reviewed and refined the matrix to ensure accuracy, completeness, and consistency in data representation. To enhance rigor, discrepancies were discussed and resolved collaboratively. The full analytic team then conducted a review of the finalized matrix, engaging in consensus building to identify cross-cutting concepts and key insights.

Ethical Considerations

This study was deemed an exempt human research study by the Colorado Multiple Institutional Review Board (17-1153) and did not require informed consent. All participant data were handled in accordance with institutional privacy and confidentiality guidelines.

Results

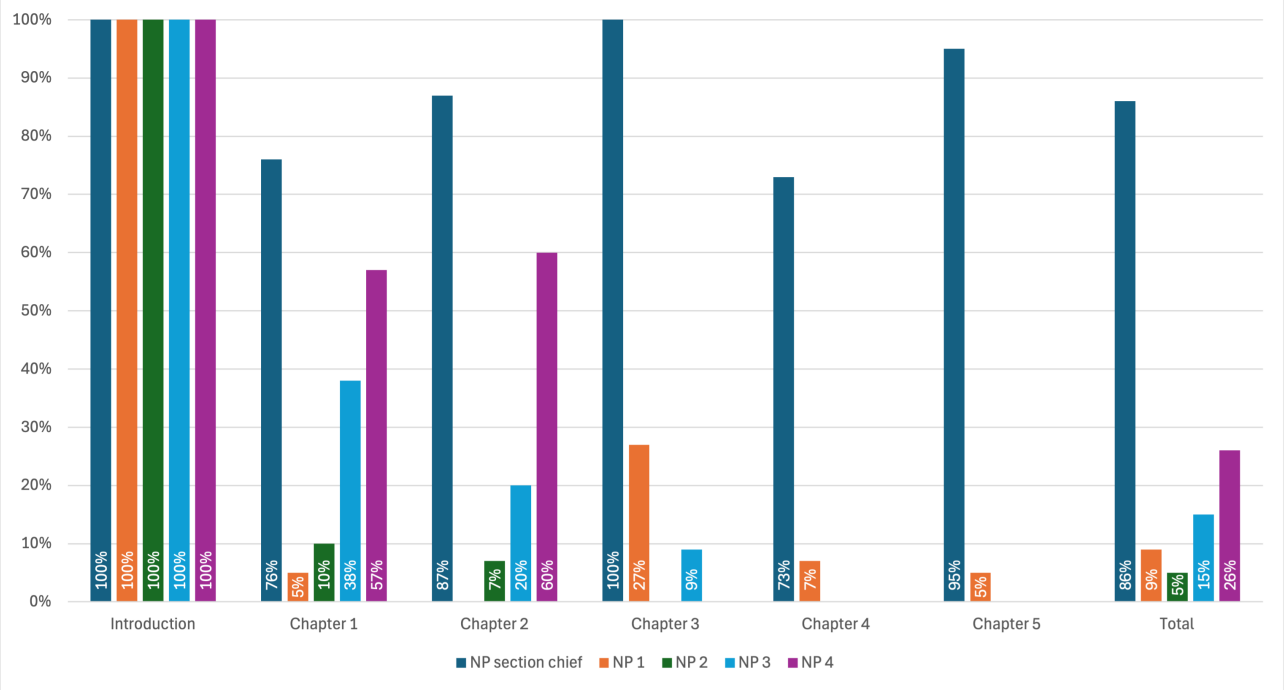
The NP section chief and 4 cardiology NP team members participated in the study, with the NP section chief acting as the primary implementer and evaluator due to their formal supervisory role. The NP team provides clinical care across various inpatient and outpatient settings (eg, heart failure clinic and structural heart and valve clinic) and meets virtually each month for updates and professional development.

Acceptability, Appropriateness, and Feasibility and Platform Visits

The NP section chief, the primary participant, strongly agreed (5/5) on all measures that the Relational Playbook on the Whistle platform was acceptable (Acceptability of Intervention Measure), appropriate (Intervention Appropriateness Measure), and feasible (Feasibility of Intervention Measure). They engaged with 86% (73/85) of the learning content and reflection surveys and adopted all 11 kick-off interventions at least once with their team. The 4 cardiology NP team members engaged fully with the introduction, and their engagement declined over the subsequent 5 chapters. During scheduled check-ins, NP team members reported that their busy schedules, their direct care responsibilities, and not leading their own teams made it harder for them to implement the Relational Playbook interventions as they were not directly applicable to their roles. They found the learning components valuable and noted that these resources enhanced their understanding of and engagement in the section chief's activities. However, the lack of applicability in their daily work led to disengagement with the platform. Figure 2 shows the completion rates by chapter for the Whistle-enabled Relational Playbook.

The NP section chief provided generally positive feedback on the kick-off interventions and reported that their team adopted a more positive outlook, identifying what mattered most to them, such as "'family,' 'friends/relationships,' 'fulfilling my responsibilities,' and 'being good at my job.'" They had specific successes with using debriefs:

> *Worked well with a co-worker to solve a problem!*



However, the *Walk in My Shoes* and *Was It Worth It* interventions were more challenging to implement, as the NP section chief explained:

> *...I think it needs to be the right timing and people.*

They also reported adapting some interventions, such as replacing the "Stop, Start, Continue" group discussion with an online survey and incorporating the "What was a win this week" question from chapter 4 as a meeting icebreaker.

XSL•FO
RenderX

Figure 2. The Relational Playbook on Whistle completion rates. This figure displays the chapter completion rates for each participant alongside their total completion rate for the entire program. While all participants completed the introduction chapter, participation rates declined for everyone but the nurse practitioner (NP) section chief for chapters 1 to 5.

Interview Results

Platform Usability and Learning Content

The NP section chief primarily used the website, rating it as easy to use (4 out of 5 on a verbal ease-of-use scale) and preferable to the mobile app, which required frequent log-ins and multiple clicks to access content. They appreciated the ability to navigate seamlessly through the program and liked the push notifications (ie, nudges). The Relational Playbook content was described as "bite size enough to be done in one sitting and...easily digested." However, they observed that the Relational Playbook was designed for teams that "work together in a clinical way." Considering that the NP group did not physically work together, they suggested modifying the content to better reflect virtual team dynamics.

Relational Playbook Implementation

The NP section chief rated the implementation of the Relational Playbook practices as moderately easy (3 out of 5 on a verbal ease-of-implementation scale). They confirmed that the practices fostered a more positive team outlook, stating the following:

> *...there's some hard days.... And we focus a lot on the negative...instead of what went right. I liked that about the Playbook.*

They emphasized that the learning content only took 5 to 10 minutes to complete. Overall, the NP section chief described the Relational Playbook on Whistle as a valuable program:

> *You can always improve as a leader—I highly recommend it.*

Adaptations and Sustainment

The NP section chief suggested adaptations before expanding the program: (1) tailor Relational Playbook content for virtual teams that do not meet routinely in person, (2) condense the program to 6 months (from 1 year), (3) reduce nudges to every other week (from weekly), and (4) develop an educational module for team members without formal leadership roles. At the conclusion of the 1-year program, the NP section chief reported ongoing use of the huddles and appreciative inquiry practices.

Discussion

This feasibility study demonstrated that the Relational Playbook on Whistle is an acceptable, appropriate, and feasible intervention for a nurse leader. The NP section chief engaged with 86% (73/85) of the educational content and implemented all 11 kick-off interventions, confirming the platform's usability. Participant feedback emphasized the Relational Playbook's strengths, including its concise, "bite-sized" content; intuitive navigation; and direct relevance to clinical practice. By applying Relational Playbook practices, the NP section chief fostered a culture of learning and positivity within the team. The NP clinical team accessed the platform and participated intermittently. This may reflect the absence of opportunity for practicing NPs to put the leadership interventions into practice, the unique challenges of virtual teams that do not routinely work in person (noted above), or the assumption that leadership development is only for those who have formal leadership titles. Their reports of finding the education components valuable reinforce the section chief's recommendation for an educational module for team members without formal leadership roles.

The Whistle platform behavioral science features guided participants to set learning intentions, assume responsibility for their goals, and receive feedback on progress. While our study data did not allow for a granular analysis of each feature's individual contribution to engagement, this is an area that we

XSL•FO
RenderX

will explore in future research. Rapid application of newly acquired skills in practice represents the gold standard of leadership development programs. Our single-team study process and findings align with recent work by Güntner et al [23], which reported that a web-based leadership transfer intervention positively influenced leaders' mindsets and self-regulated learning. The significance of these studies lies in demonstrating that digital microlearning interventions can effectively support leadership development in high-demand clinical environments, offering a scalable and cost-efficient alternative to traditional programs. Future studies of the Relational Playbook on Whistle will advance the evidence base for digital leadership training programs, ensuring positive outcomes in a cost-effective manner.

The partnership with Whistle Systems was an opportunity to integrate an evidence-based leadership development program into a digital technology innovation that delivered microlearning content using behavioral science and gamification principles. This technology overcame time constraints, a common barrier for busy nurse leaders [24,25], and promoted engagement and new habits. The Whistle platform's usability was rated favorably by the NP section chief, with the website preferred over the mobile app due to frequent re–log-ins and navigation challenges. Nudges effectively promoted engagement by linking directly to assigned content; however, a decrease in frequency was suggested to reduce response burden.

Additional behavior-driving tools offered by the Whistle platform were not leveraged in this feasibility study that could increase engagement and effectiveness among team members. These include real-time automated acknowledgments; hospital-branded Visa cards for monetary reward; peer or community recognition engagement through Whistle's "Town-Square" social feature; or the platform's artificial intelligence engine Robin, which tailors nudges informed by behavioral personalization algorithms to effectively prompt individuals while considering their unique motivational drivers [19]. Future iterations of the Relational Playbook on Whistle will include an educational module for team members in clinical roles to motivate them to learn and engage in culture change, content for virtual and hybrid teams, and additional Whistle tools.

This study's strengths include the real-world evaluation of the Relational Playbook on Whistle and its focus on clinical leadership development. The feasibility approach provided early insights into implementation outcomes, user experience, and potential program impact. However, several limitations should be noted: the small sample size and single-team design, reliance on 1 primary participant, absence of a control group, and lack of objective leadership or patient-related outcomes reduce the ability to attribute observed changes to the intervention. These factors limit generalizability, and findings should be interpreted with caution. Future research will address these limitations by including a larger, more diverse sample; detailed demographic data; a comparison group; and multisource ratings to capture changes in leader behavior and team culture before and after implementation.

The Relational Playbook on Whistle shows strong promise as an acceptable, appropriate, and feasible nurse leadership development program capable of addressing critical workforce challenges such as burnout, team dynamics, and leadership readiness. To maximize its impact, future iterations should include adaptations for virtual teams, streamline program delivery, actively engage all team members, assess the impact on patient safety, and evaluate cost-effectiveness compared to traditional leadership programs. Scaling the Relational Playbook across diverse clinical settings will require strategic collaboration with technology partners to ensure accessibility, flexibility, and sustained implementation. By leveraging digital platforms for leadership development, health care organizations can accelerate skill acquisition, strengthen team culture, and build resilient leaders in an increasingly complex care environment.

Abstract

Background: Mobile health (mHealth) technology offers new approaches to improve women's health by providing personalized monitoring and real-time guidance. As one of the most widely used social media platforms in China, WeChat has shown great potential in mHealth practice, yet systematic evidence on its application in women's health care remains insufficient.

Objective: This study aims to systematically review WeChat-based nursing interventions in women's mHealth in order to clarify the application status, intervention modalities, target populations, and effectiveness outcomes.

Methods: Searches were conducted in IEEE Xplore, Web of Science, PubMed, Scopus, ACM Digital Library, and Cochrane Central Register of Controlled Trials between January 2011 and December 2024. Two independent reviewers screened studies; extracted data on study design, intervention forms, target diseases, and outcome indicators; and assessed methodological quality. The Cohen κ coefficient was used to evaluate interreviewer agreement. Publication trends, institutional collaborations, author contributions, and research hotspots were analyzed using VOSviewer (Leiden University) and InCites (Clarivate) for bibliometric analysis.

Results: A total of 31 eligible studies published from 2014 to 2024 were included. Most studies were randomized controlled trials (n=27). Intervention modalities mainly included WeChat groups (n=22), official accounts (n=18), applets (n=4), and private chats (n=9), mostly used in combination. The top focused health issues were prenatal care (n=5), breast cancer (n=5), gynecological cancer (n=5), and gestational diabetes mellitus (n=4). Six studies adopted multidisciplinary teams. Cohen κ was 0.71, indicating substantial agreement. Publications grew rapidly after 2018, peaking in 2021 and 2024. A total of 40 institutions participated, with Xi'an Jiaotong University having the highest citation impact. Most studies were at high risk of bias due to a nonblinding design.

Conclusions: WeChat-based nursing interventions improve personalized health information access, self-management ability, treatment compliance, and real-time doctor-patient communication for women. This is the first systematic review to evaluate WeChat mHealth interventions in women's health, filling the research gap. Future research should focus on improving methodological quality, exploring cross-cultural adaptability, conducting long-term follow-up, and integrating wearable devices and electronic health records to further optimize WeChat-based women's health services.

KEYWORDS

WeChat; mobile health; mHealth; bibliometric; applet; women

Introduction

Women face unique health issues at different life stages [1]. In adolescence, the onset of menstruation may bring challenges like dysmenorrhea or polycystic ovary syndrome [2], while reproductive years often involve fertility management, prenatal care, and pregnancy-related conditions [3]. During midlife, menopause introduces hormonal fluctuations that can trigger

XSL•FO
RenderX

hot flashes, osteoporosis, and mood disorders [4]. Even beyond menopause, postreproductive years confer increased risks of cardiovascular disease, breast cancer, and cognitive decline [5,6]. Furthermore, women tend to be more vulnerable to anxiety and depression than men, owing to a mix of biological, psychological, and social elements [7]. Therefore, safeguarding women's health is an important task in the public health field. It not only concerns their own quality of life but also correlates with the overall development of society.

With the quick development of information technology, mobile health (mHealth) offers a new avenue for improving women's health. It refers to leveraging mobile devices, like smartphones and wearables, to provide accessible and tailored health care services [8]. For instance, women may use the Oura ring to track their sleep, temperature, and heart rate during the menstrual cycle, which helps find early health warning signs [9]. A high usage of the SmartMoms app in pregnant women exerts a positive effect on moderate to vigorous physical activity. Additionally, mHealth tools can provide nutrition guidance and exercise advice for pregnant and postmenopausal women [10]. Some may even promote screening attendance and promote timely preventive health care behaviors [11]. Overall, mHealth is transforming women's health care by supporting their varied needs and making health interventions more accessible and effective.

In China, WeChat stands out as a major social media platform with a substantial user population. According to Tencent's 2025 annual earnings report [12], WeChat had more than 1.3 billion monthly active users as of March 2025, covering most of China's internet users. This phenomenon renders the WeChat platform as an effective mHealth platform for women's health [13,14], with several key advantages. First, its large user base allows accurate delivery of health information and services. Second, users can share health care information online [15,16]. Third, applets can be developed into practical health management tools [17]. However, despite its convenience, it still lacks systematic reviews on the WeChat app in women's health care.

Previous reviews have evaluated the effects of mHealth interventions on women's health outcomes, but they did not distinguish between different mHealth delivery modalities [18,19]. In particular, WeChat-based interventions were not separately analyzed in prior syntheses. Meanwhile, existing reviews that involve WeChat have centered on chronic conditions such as cancer [20], mental health [21,22], and diabetes [23], without focusing on the full life cycle of women's health. Under this context, it is essential to systematically explore the application, effectiveness, and implementation of WeChat-based mHealth interventions in women's health to fill this important evidence gap.

This systematic review aims to comprehensively and systematically collect and analyze relevant research on women's mHealth apps based on the WeChat platform, summarizing their application status, effectiveness, and existing problems. By comprehensively evaluating WeChat's apps in all aspects of women's health monitoring, disease prevention, and health management, it provides a scientific basis for further optimizing the application of WeChat in women's mHealth. At the same time, this study helps to identify research gaps and development trends in this field, providing directions for subsequent research and practice. Thus, it can better use the WeChat platform to improve women's health levels, filling the gaps in existing research, and has important theoretical and practical significance.

Methods

Study Design

This review was registered in the PROSPERO International Prospective Register of Systematic Reviews (CRD420251051789) and followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines closely in its conduct and reporting (Checklist 1) [24].

Research Question

This systematic review aimed to explore the research question: How effective are WeChat-based nursing interventions in enhancing health outcomes for women at various life stages, and what is their current implementation status? The design of the review adhered to the PICO framework:

1. Population (P): Women of all ages and life stages (adolescence, reproductive years, pregnancy, postpartum, menopause, and postmenopausal periods) with various women-related health conditions.
2. Intervention (I): WeChat-based nursing interventions (WeChat groups, official accounts, applets, and private chat) for health education, care management, psychological support, and multidisciplinary collaborative care.
3. Comparison (C): Standard routine care, usual hospital follow-up, or no additional WeChat-based intervention.
4. Outcomes (O): Clinical indicators, quality of life, self-management ability, treatment compliance, psychological status, satisfaction, and behavioral outcomes.

Database Selection and Search Strategy

An extensive search plan was formulated by using free-text words and subject headings. The following databases were explored from January 2011 to December 2024: IEEE Xplore, Web of Science, PubMed, Scopus, ACM Digital Library, the Cochrane Central Register of Controlled Trials, and the China National Knowledge Infrastructure (CNKI). An effective retrieval strategy was established using a 2-step process. The first step involved collecting and organizing relevant search terms from related systematic reviews and meta-analyses [25,26]. Afterward, 3 authors (RL, YW, and TW) carefully examined and improved these terms to guarantee thorough inclusion of all essential terms. Using Boolean logic operators, the concluding search strategy was designed: ("wechat" or "weixin" or "official account" or "public account" or "applet" or "mini program") and (medic* OR illness* OR disease* OR health* OR pharma* OR drug* OR therap*) and (woman OR women OR girl OR female). The full search strategy for each database is detailed in Table 1. Additionally, we did not impose any restrictions on health-related keywords in the Cochrane Central Register of Controlled Trials database, because we

XSL•FO
RenderX

assumed that all documents in this database are related to human health by default, so that we can cover a wider range of potential literatures. Since numerous relevant studies have been published in Chinese, we specifically included CNKI. Other ways to identify studies involved expert recommendations and manually searching the references of included studies and pertinent systematic reviews.

Table . Specific search terms of databases.

Database	Search term	Studies, n
IEEE Xplore	((((All Metadata:“Wechat") OR (All Metadata:"weixin") OR (All Metadata:"official account") OR (All Metadata:"applet") OR (All Metadata:"Mini Program"))) AND ((All Metadata:medic*) OR (All Metadata:illness*) OR (All Metadata:disease*) OR (All Metadata:health*) OR (All Metadata:pharma*) OR (All Metadata:drug*) OR (All Metadata:therap*))) AND ((All Metadata:"woman") OR (All Metadata:"women") OR (All Metadata:"girl") OR (All Metadata:"female”))	6
Web of Science	((TS=(“Wechat” or “weixin” or “official account” or “applet” or “Mini Program”)) AND TS=(medic* OR illness* OR disease* OR health* OR pharma* OR drug* OR therap*)) AND TS=(“woman” or “women” or “girl” or “female”)	629

Retrieved records were first imported into EndNote X21. Duplicate records were identified using the automatic deduplication tool, and a manual check was conducted to remove any duplicates left due to differences in author names, publication formats, or metadata entries.

Screening Process

The titles and abstracts were independently reviewed by two reviewers (JX and RL) following a step-by-step process using the established inclusion and exclusion criteria (Table 2). Any discrepancies were resolved through discussion until consensus; if unresolved, a third senior reviewer (TW) adjudicated the final

XSL•FO
RenderX

decision. Cohen κ was used to assess the agreement between the reviewers.

Table . Inclusion and exclusion criteria for title and abstract screening.

Framework	Inclusion criteria	Exclusion criteria
Population	• Women of all age groups and life stages with related health conditions	• Non-female-specific diseases (asthma, appendicitis, etc)
Intervention	• WeChat-based mHealth interventions in women (health education, symptom monitoring, care management, psychological intervention, etc) • Focused on nursing-led or nursing-coordinated interventions, determined by the actual intervention content, the first/corresponding author's nursing department affiliation, and author contribution statements	• Investigated the relationship between WeChat use and other factors (mental health, etc) • Computational analytical studies (content analysis, framework development, etc) • Merely used WeChat for questionnaire distribution and data collection, with no active health intervention • Irrelevant to WeChat-based mHealth interventions
Comparison	• Standard care and follow-up	• Not available
Outcomes	• Clinical indicators, psychological status, self-management, compliance, and other health-related outcomes	• Not available
Study design	• Original research articles • Interventional studies (randomized controlled trials and quasi-experiments) • No language restrictions	• Clinical trial protocols • Noninterventional designs (cross-sectional, cohort, case series, etc) • CNKI[a]-sourced literature outside Chinese core journal databases (Peking University Core, CSCD[b], Chinese Science and Technology Core Journals)

[a]CNKI: China National Knowledge Infrastructure.

[b]CSCD: Chinese Science Citation Database.

Quality Appraisal

The Cochrane risk-of-bias tool [27] and Risk of Bias in Nonrandomized Studies of Interventions (ROBINS-I) [28] were used to assess the quality of randomized controlled trials (RCTs) and quasi-experiments, respectively. Both instruments encourage assessment of internal and external validity and aid in evaluating methodological quality and clarity in reporting. Two independent reviewers (JX and RL) conducted the quality assessment for all studies. Any disagreements were resolved through discussion or by involving a third reviewer (TW).

Data Preprocessing and Extraction

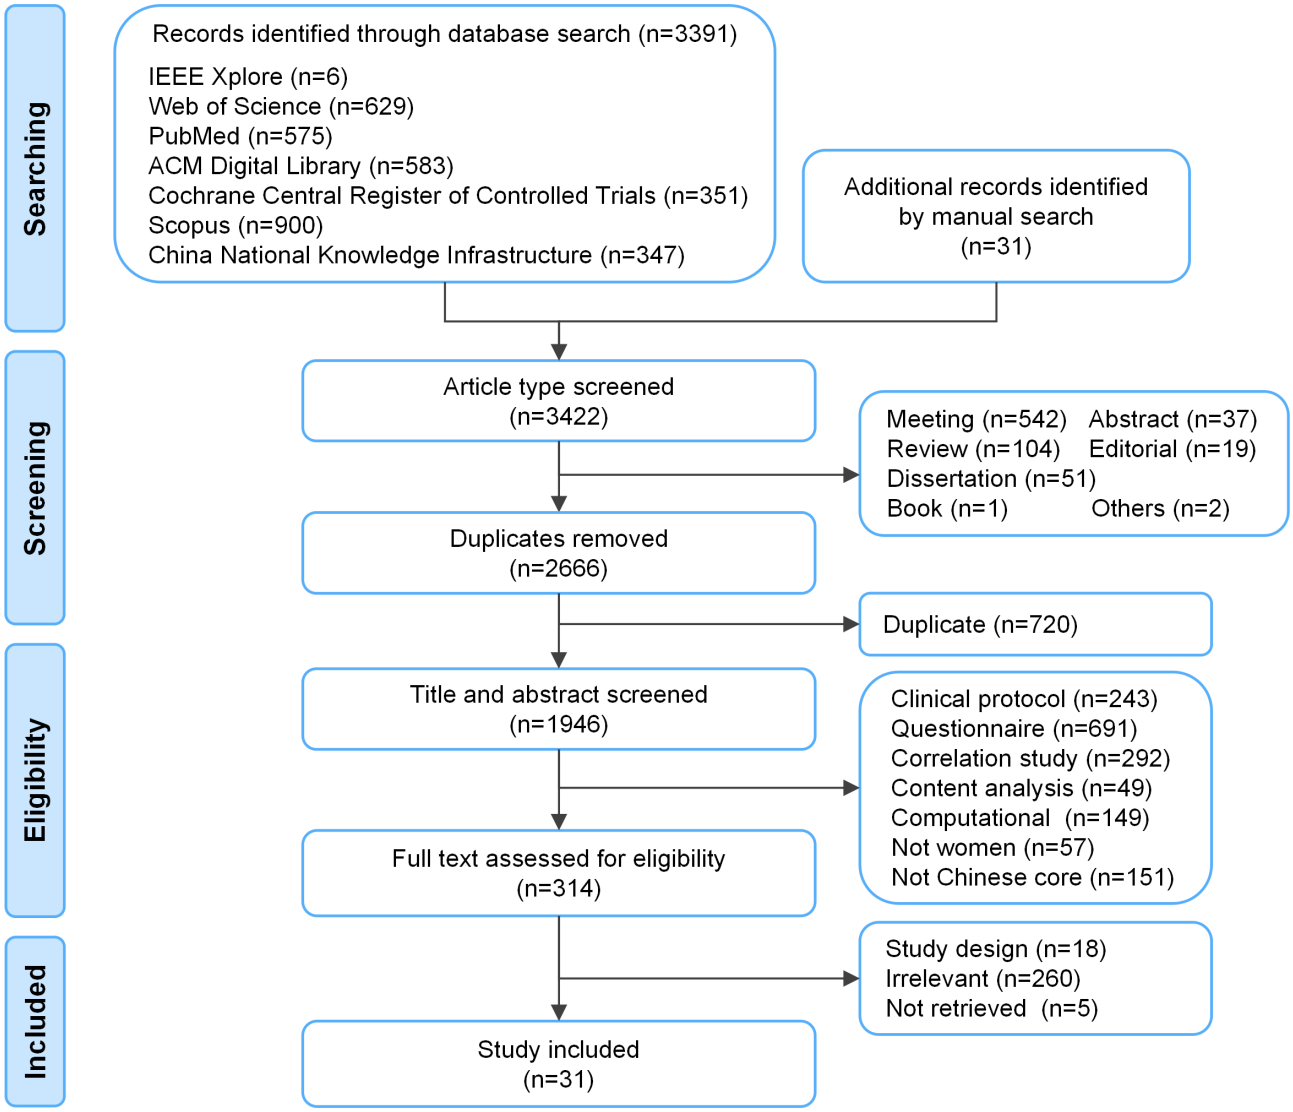
To support subsequent bibliometric analysis, records from all databases were standardized and manually adjusted to align with the Web of Science format. For studies with missing bibliometric information (eg, incomplete affiliation, citation counts, or journal metadata), supplementary information was manually retrieved from the original full text.

Before bibliometric analysis, data were systematically cleaned and standardized using the *bibliometrix* R packages. To ensure consistency, author names were standardized in terms of abbreviations, initials, and sequence. For example, different versions like "Zhang, San," "Zhang, S.," and "San Zhang" were unified into a consistent format. Synonyms, aliases, and different singular/plural versions of keywords were also unified. For example, "mini-program," "mini program," and "applet" were unified into a single term. Other core bibliographic information, such as first/corresponding authors, countries, affiliations, and journals, were also standardized. Ultimately, the cleaned bibliographic records were converted into a structured data frame, making them ready for further bibliometric analysis.

Given the diverse women's health conditions, the small number of studies per condition, and clinical heterogeneity across included studies, a narrative descriptive synthesis was prespecified as the primary outcome analysis method. One reviewer (JX) independently extracted all data from each included study using the predefined form. Extracted items included author, publication year, country, study setting, study design, objectives, sample size, participant characteristics, intervention details, outcome measures, and key findings. A second reviewer (RL) independently verified all extracted data for accuracy and completeness. Discrepancies between the two reviewers (JX and RL) were resolved through discussion and consensus. If no agreement was reached, a third reviewer (TW) made the final decision. For missing study-level data, we only extracted and analyzed available valid data. No imputation or statistical filling was performed for missing data. The review adhered strictly to the registered protocol, with no deviations from the study plan.

XSL•FO
RenderX

Bibliometric Metrics



VOSviewer (Leiden University) and InCites (Clarivate) were used to quantify the knowledge structure and emerging research trends. VOSviewer 1.6.18 was used to cluster institutions and researchers. To standardize terminological variations, a custom thesaurus file was used. Association strength normalization was applied, with attraction and repulsion values set at 3 and −1. Clustering was conducted using a resolution parameter of 1.0 and a minimum cluster size of 1, resulting in a network with 21 items, 103 links, and a total link strength of 106. The total citation impact was divided by the number of years since publication to determine the yearly citation impact. The H-index signifies that an author has H articles cited no less than H times.

Results

Process of Screening

Figure 1 presents a PRISMA flow diagram summarizing the screening process and exclusions. The electronic databases yielded 3391 records, and an extra 31 were found by manually searching journals, bringing the total initial number of records to 3422. After excluding nonoriginal articles and duplicates, the remaining 1946 records proceeded to title and abstract assessment. Of these, 1632 were excluded at this stage, and 314 full-text articles were assessed for eligibility. Finally, a set of 31 studies was included in the data extraction. Cohen κ was calculated to be 0.71, which suggests a substantial level of agreement.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.

Basic Characteristics of Eligible Studies

The review systematically included 31 studies that appeared in publications between 2014 and 2024 (Table 3). Overall, 17 provinces participated in this research discourse, with the majority of publications originating from Beijing (n=5) [29-33], Shanghai (n=5) [34-38], Shanxi (n=3) [39-41], Liaoning (n=3) [42-44], and Zhejiang (n=3) [45-47]. Regarding the research type, 27 were RCTs and 4 were quasi-experiments [34,48-50], respectively.

XSL•FO
RenderX

Table . Study design, intervention modalities, and main outcomes of included studies.

Reference	Study design	Modality	WeChat intervention	Grouping and duration	Primary outcome
Prenatal care					
Guan et al [42] (2014)	RCT[a]		Establish a WeChat group and send prenatal examination times and prenatal education.	① Intervention (n=109) ② Usual care (n=109)	Higher rate of vaginal delivery, fewer negative emotions, and postpartum blood loss in ① than ②.
Huang et al [34] (2019)	QE[b]		Establish an official account to push intervention information.	① Intervention (n=69) ② Usual care (n=69) *t*=13 weeks	Higher health belief in ① than ②. No significant behavior compliance and knowledge level.
Chen et al [48] (2020)	QE		Share gestational knowledge, send course schedules, and push individualized prenatal care information.	① Intervention group (n=83) ② Regular examination (n=85) *t*=Until delivery	Higher number of prenatal examinations in ① than ②.
Gu et al [37] (2024)	RCT		Make 8 appointments for midwife-led antenatal home visit services in the outpatient department and handling routine matters.	① Intervention (n=485) ② Usual care (n=499) *t*=Until delivery	Lower cesarean section rate, chances of epidural analgesia, and NICU[c] admission, less amount of bleeding in the third stage of labor and 2 hours postpartum, and less amount of total bleeding in ① than ②.
Wang et al [51] (2024)	RCT		Based on the various stages of pregnancy, the intervention plan was formulated, incorporating motivation, ability, and trigger steps in each segment.	① Online and offline management (n=29) ② Standard care (n=48)	Reduced gestational weight gain, increased the appropriate weight gain rate, and improved perinatal outcomes in ① than ②.
Breast cancer					
Zhou et al [39] (2020)	RCT		A multimodal nursing program offers guidance, education, and support on physical, mental, and social dimensions.	① Intervention (n=56) ② Routine care (n=55) *t*=6 months	Higher health-related quality of life during early rehabilitation in ① than ②. Comparable effects on pain, fatigue, and sleep disturbances in ① and ②.
Xu et al [52] (2021)	RCT		Establish a WeChat medical service team to create case management files and conduct health education.	① Intervention (n=63) ② Routine care (n=63)	Improved self-efficacy, quality of life, and satisfaction in ① than ②.
Xu et al [32] (2022)	Self-before-and-after		Join a WeChat group and explore the official account concerning complex decongestive therapy. The intensive phase spanned 1 month, and the maintenance phase was perpetual with weekly online instructions.	Received complex decongestive therapy with WeChat (n=61) *t*=3 months	Reduced excess arm volume, relieved lymphedema symptoms, and improved the quality of life after treatment.

XSL•FO
RenderX

Reference	Study design	Modality	WeChat intervention	Grouping and duration	Primary outcome
Wu et al [47] (2021)	RCT		Group management and public account for education of patient's family.	① Intervention (n=43) ② Usual care (n=43) *t*=3 months	Improved function of the affected limb, psychosocial adjustment ability, functional exercise compliance, quality of life, and nursing satisfaction in ① than ②.
Wang et al [38] (2024)	RCT		A nursing program with multiple modes delivers details on physical, psychological, and social rehabilitation.	① Intervention (n=62) ② Routine care (n=63) *t*=Until 6 months post-surgery	Reduced fear of cancer recurrence and increased health-related quality of life in ① than ②.
Gynecological cancer					
Zou et al [53] (2018)	RCT		WeChat preoperative education includes psychological nursing, disease, HIFU,[d] and the possible complications.	① Intervention (n=251) ② Usual care (n=175)	Reduced anxiety before and after surgery, decreased pain after surgery, and greater satisfaction with the treatment in ① than ②.
Lu et al [46] (2021)	RCT		Establish an educational management group and provide targeted psychological intervention.	① Baofukang (n=50) ② Baofukang + Lactobacillus (n=50) ③ Baofukang + Lactobacillus + WeChat (n=50) *t*=3 months	Higher rate of lesion reversal, total effective rate, cognitive score in ③ than ① and ②.
Han et al [40] (2021)	RCT		Multidisciplinary nursing collaboration is maintained continuously through WeChat, telephone, and face-to-face discussions.	① Intervention (n=66) ② Regular care (n=66) *t*=3 months	Attenuated anxiety and depression, higher physical functioning, general health, and mental health in ① than ②.
Li et al [41] (2023)	RCT		Deliver psychoeducation, skills training, and counseling through the official account "Hand in Hand."	① WeChat couple-based psychosocial support (n=49) ② Eight WeChat articles (n=49) *t*=2 months	Higher relationship satisfaction and quality of life in ① than ②. Comparable effect on sexual function in ① and ②.
Tian et al [33] 2024	RCT		Join the nutrition management group on the "Good Nutrition" applet and send a private message for consultation.	① Intervention (n=48) ② Usual care (n=48)	Improved nutritional status in ① than ②. Significant altered nutrition-inflammation composite indices in ① and ②.
Gestational diabetes mellitus					
Tian et al [30] (2021)	RCT		Patients share self-management experiences based on provided learning materials.	① Intervention (n=147) ② Standard care (n=162) *t*=Until delivery	More effective for blood glucose control in ① than ②. Pregnancy outcomes showed no significant differences.

Guo et al [54] (2021)	RCT		Establish a WeChat group, and push GDM[e]-related knowledge, conduct one-to-one guidance weekly and followed up online.	① Intervention (n=70) ② Routine care (n=70) *t*=Until delivery	Blood glucose levels, mental state, self-management behavior, quality of life, and pregnancy outcomes were better in ① compared to ②.
Deng et al [31] (2022)	RCT		Remind participants to record diet and exercise diaries and post photos.	① Intervention (n=47) ② Routine care (n=47) *t*=Until delivery	Fewer GDM in ① than ②. Weight gain did not differ significantly.
Wang et al [49] (2024)	QE		Pregnant women were guided offline on diet, exercise, etc, and used applet to upload data for online guidance.	① Intervention (n=26) ② Routine care (n=26) *t*=Until delivery	Reduced 2-hour postprandial glucose, improved self-management ability and blood glucose management satisfaction in ① than ②.
Breastfeeding					
Wu et al [29] (2020)	RCT		Push breastfeeding knowledge and promotion information through “Ke Xue Wei Yang.”	① Intervention (n=170) ② Routine care (n=174) *t*=Until 6 months postpartum	During the first month after birth, the rate of exclusive breastfeeding was greater in ① compared to ②.
Yu et al [55] (2021)	RCT		Deliver breastfeeding education and parenting insights, foster the mother-child relationship, and provide guidance on life specifics.	① Intervention (n=30) ② Usual care (n=30) *t*=3 months	The scores for breastfeeding efficacy and satisfaction, along with the exclusive breastfeeding rate, are superior in ① than in ②.
Polycystic ovary syndrome					
Sang et al [56] (2022)	RCT		Patients report personal information and communicate with medical staff through WeChat.	① Intervention (n=39) ② Standard care (n=40) *t*=3 months	Improved weight loss and oocyte quality, and increased the live birth rate in ① than ②.
Dilimulati et al [36] (2024)	RCT		An applet with 3 modules: watching 2 videos about healthy lifestyle per week, recording health information, and self-selected reading. A doctor coached the patients weekly.	① Intervention (n=40) ② Metformin (n=40) *t*=3 months	Comparable insulin resistance in ① and ②. ① better than ② in reducing waist circumference, waist-to-hip ratio, total fat mass, and dehydroepiandrosterone sulfate. ① fewer than ② in adverse events.
Pregnant with psychological distress					
Yang et al [45] (2019)	RCT		Join 4 mindfulness courses and a WeChat group to share experiences with researchers.	① Intervention (n=62) ② Routine care (n=61) *t*=2 months	Reduced depressive and anxious symptoms, as well as improved mindfulness skills in ① than ②.
Zhang et al [57] (2023)	RCT		Reminder to participate in thematic lessons in video format and homework, such as mindful breathing and body scan practices.	① Intervention (n=80) ② Usual care (n=80) *t*=6 weeks	Reduced maternal depression and anxiety in ① than ②. More favorable temperament scores of infants in ① than ②.

Postpartum care					
Li et al [58] (2020)	RCT		Push health education information via "maternal health care standard during pregnancy."	① WeChat (n=350) ② Specialist team (n=350) ③ WeChat-specialist team (n=350) ④ Routine care (n=350) *t*=Until 7 weeks postpartum	Enhanced quality of maternal health care services in ①②③ than ④. ④ had the largest effect on both primary and secondary outcomes.
Chu et al [35] (2024)	RCT		Deliver daily training reminders and see videos guiding pelvic floor muscle training.	① Intervention (n=76) ② Control (n=72) *t*=6 weeks	Increased adherence rate, improved peak surface electromyography, and contraction endurance in ① than ②. Comparable stress urinary incontinence symptoms in ① and ②.
Others					
Wang et al [43] (2021)	RCT (gynecological inflammatory disease)			① Intervention (n=160) ② Usual care (n=160) *t*=3 months	The quality of nursing, understanding of gynecological health knowledge, and satisfaction level are higher in ① compared to ②.
Su et al [44] (2016)	RCT (primary dysmenorrhea)			① Intervention (n=90) ② Routine care (n=90) *t*=3 months	Improved knowledge, attitude, behavior, and reduced pain intensity in ① than ②.
Li et al [59] (2017)	RCT (infertility)			① Intervention (n=300) ② Usual care (n=300) *t*=3 months	Improved understanding of assisted reproduction, greater effectiveness in managing one's own cycle, self-efficacy, and satisfaction, lower degree of anxiety in ① than ②.
Yu et al [50] (2023)	QE (pelvic organ prolapse)			① Intervention (n=40) ② Routine care (n=40)	Improved cognition, compliance, pelvic floor function, muscle strength, and quality of life in ① than ②.

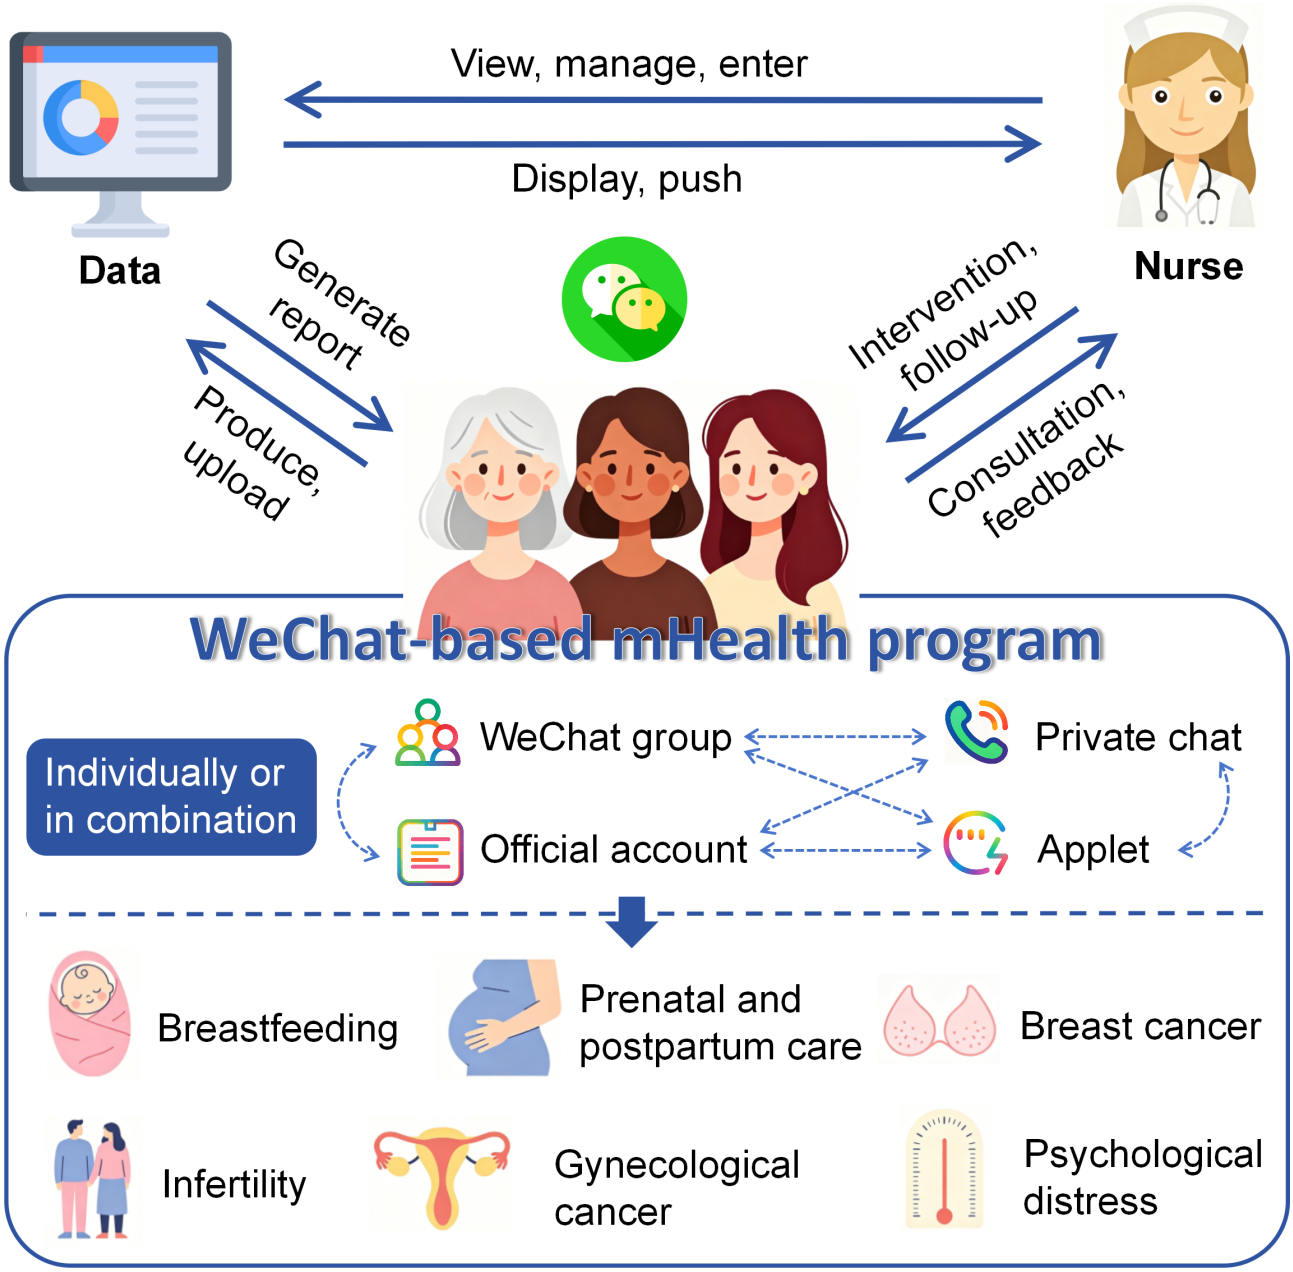
[d]HIFU: high-intensity focused ultrasound.

[e]GDM: gestational diabetes mellitus.



Intervention Method

In most studies, the control group received standard care, which included routine patient education and health management. For pregnant women, standard care typically involves regular classes at the maternity school and scheduled telephone follow-ups (Figure 2) [49]. The mHealth group comprises standard care plus WeChat interventions, which fall into 4 categories: WeChat group, official account, private chats, and applet. Twenty-two studies established WeChat groups, and participants could freely share experiences, discuss difficulties, and interact with peers and researchers at any time [30-33,37-40,43-48,50-56,58]. In these groups, all inquiries and consultations concerning the intervention were promptly handled by researchers. Nine studies used private chats for personalized follow-up communication, often in conjunction with group-based activities [33,35,38,40,42,44,54,56,59]. Eighteen studies delivered health-related information via official accounts to enhance the

XSL•FO
RenderX

knowledge of diseases [29,32,34,35,37,39,41,42,44,47,48,50-52,54,55,58,59]. Some of these studies released original content, while others shared and reposted existing credible popular science articles from other sources. Four studies were developed to achieve more individual interaction [33,36,49,57]. An applet usually contains several modules, including a symptom assessment instrument and a health education knowledge base. They could also provide educational videos and check-in tasks [36]. Notably, 19 of the 31 studies used 2 or more intervention components in combination, indicating that combined WeChat-based strategies are common in mHealth interventions.

Figure 2. Conceptual logic of interventional studies, illustrating the full workflow, participant interaction patterns, and service components of WeChat-based nursing interventions. mHealth: mobile health.

Conditions Involved

The most studied diseases include prenatal care (n=5) [34,37,42,48,51], breast cancer (n=5) [32,38,39,47,52], and gynecological cancer (n=5) [33,40,41,46,53], followed by gestational diabetes mellitus (n=4) [30,31,49,54], breastfeeding (n=2) [29,55], polycystic ovary syndrome (n=2) [36,56], pregnant with psychological distress (n=2) [45,57], and postpartum care (n=2) [35,58]. There is only one study for gynecological inflammatory diseases [43], primary dysmenorrhea [44], pelvic organ prolapse [50], and infertility [59].

Main Effectiveness of WeChat-Based Nursing Interventions

Prenatal Care

A total of 5 studies investigated WeChat-based interventions for prenatal care. Huang et al [34] reported no significant improvement in knowledge level or behavioral compliance despite increased health beliefs, whereas another two studies

XSL•FO
RenderX

showed improvements in both knowledge and adherence [42,48]. Three studies found a lower cesarean section rate [37,42,51], and two of them reported reduced postpartum hemorrhage [37,42].

Breast Cancer

All 5 studies demonstrated that WeChat-based nursing interventions exerted favorable effects on psychological recovery and quality of life on women with breast cancer. Liang et al [32] exclusively assessed objective lymphedema-related outcomes and demonstrated clear relief of lymphedema. Wang et al [38] uniquely measured fear of cancer recurrence, which was significantly reduced in the intervention group. Xu et al [52] focused on self-efficacy and treatment-related discomfort, both of which showed significant benefits. Despite no studies reporting conflicting or opposite results, 2 studies consistently found that pain, fatigue, and sleep disturbance showed no statistically significant between-group differences [38,39].

Gestational Diabetes Mellitus

Altogether, 4 studies evaluated WeChat-based interventions for glycemic management in women with gestational diabetes mellitus [30,31,49,54]. All studies confirmed significant improvements in glycemic control (reduced fasting and 2-hour postprandial blood glucose levels, higher glycemic qualification rates), enhanced self-management ability, and lower incidence of adverse maternal and neonatal outcomes. Guo et al [54] specifically observed the improved psychological status after WeChat intervention. Tian et al [30] found that earlier intervention (23 - 24 weeks) led to more stable glucose control.

Other Conditions

Two studies explored WeChat-based interventions to support breastfeeding. Both investigations yielded similar positive findings: elevated exclusive breastfeeding rates, strengthened breastfeeding self-efficacy, and boosted parental satisfaction relative to standard care [29,55]. However, Yu et al [55] centered on feeding safety in infants with congenital heart disease, while Wu et al [29] provided a longitudinal, population-level assessment of breastfeeding behaviors in healthy mother-infant dyads.

Two studies confirmed that digitally supported lifestyle modification significantly reduced body weight and BMI, and enhanced reproductive outcomes in patients with polycystic ovary syndrome relative to standard care [36,56]. These convergent results underscore the efficacy of WeChat platforms in facilitating sustainable lifestyle changes and clinical improvement.

Two studies revealed that digital mindfulness programs significantly alleviated depressive and anxiety symptoms and enhanced mindfulness capabilities [45,57]. Notably, the study of Zhang et al [57] was the first to reveal favorable ripple effects on infant neurodevelopment, with significantly better infant temperament at 6 weeks; these benefits were partially mediated by reduced pregnancy-specific anxiety.

In terms of postpartum rehabilitation, Chu et al [35] concentrated on postpartum pelvic floor muscle training, demonstrating that daily WeChat reminders more than doubled the adherence rate. By contrast, Li et al [58] evaluated comprehensive maternal health care quality, revealing that WeChat-based health education combined with specialist team support produced the highest satisfaction, followed by specialist support alone and WeChat alone, all superior to usual care.

Multidisciplinary Participant

Six studies established multidisciplinary teams for mHealth initiatives [31,39,40,45,49,51]. In addition to physicians and nurses, midwives were typically included to support pregnant women. Psychologists or psychological counselors are incorporated in mindfulness interventions [45]. Within a diet and exercise program, nutritionists or dietitians would calculate the energy requirements for each pregnant woman, while exercise specialists provided tailored advice as necessary [31]. Pharmacists were tasked with developing medication plans for patients. To assess the quality of life in patients with cervical cancer, one study included a sex counselor [40]. When medication was required, researchers collaborated with endocrinologists to achieve optimal glucose control [49].

Trend of Publication and Citation

The total number of publications shows a fluctuating trend. Prior to 2018, only a small number of articles were released annually [42,44,59]. From 2018 to 2024, there were at least 3 articles published each year, and the number of articles published was the highest in 2021 and 2024 (n=9 both). In terms of research fields, the majority of documents were categorized under obstetrics and gynecology (n=9), health care sciences services (n=7), general internal medicine (n=5), and medical informatics (n=5). Overall, this analysis emphasizes the interdisciplinary nature of the application of WeChat in women's mHealth, which has attracted increasing interest and experienced substantial growth in recent years.

Academic Output of Institutions

Analyzing institutional publications and citations offers a thorough insight into the scientific ecosystem. Altogether, 40 institutions participated in this field (Table 4). Multiple top-tier Chinese universities, including Peking University [32], Fudan University [37], Zhejiang University [45], and Shandong University [57], participated actively, alongside international institutions such as the University of Oxford [29], the National University of Singapore [38], and the University of Texas System [57]. Notably, Xi'an Jiaotong University distinguished itself as a productive contributor to the research with the highest citations (n=109) [39-41].

High-Impact Highly Cited Studies

Among the included studies, several publications emerged as highly cited and representative works in this field. Zhou et al [39] conducted the most frequently referenced study, which assessed a WeChat-based multimodal nursing program for women recovering from breast cancer surgery, and found notable enhancements in quality of life. Another work demonstrated that an 8-week WeChat-based mindfulness intervention effectively reduced anxiety and depression in pregnant women, and established a feasible model for psychological care via WeChat [45]. Wu et al [29] demonstrated that WeChat official account-based health education significantly improved exclusive breastfeeding rates. Tian et al [30] showed that WeChat group-mediated health education and lifestyle support yielded better glycemic control than standard prenatal care among women with gestational diabetes mellitus. Collectively, these highly cited studies represented key milestones and laid the methodological foundation for WeChat-based mHealth interventions in women's health.

Risk-of-Bias Assessment

In 20 studies, the randomization process was judged to be at low risk of bias, whereas 7 studies presented an unclear risk of bias in this domain (Figure 3 and Table 5) [40,43,47,52-55]. Blinding participants and personnel to group assignments was not feasible in all studies except one due to the interventions' characteristics [45]. Lack of blinding may have altered participants' health information-seeking behaviors in the control group, potentially biasing the outcome assessment. With regard to missing outcome data, all included studies were considered to have a low risk of bias. Regarding the measurement of outcomes and selection of the reported result, all studies were rated as having a high risk of bias, primarily because blinding of outcome assessors was not performed, and the reporting of outcomes was insufficiently transparent. Overall, the risk of bias across studies was predominantly high, which should be considered when interpreting the findings.

[a]ROBINS-I: Risk of Bias in Nonrandomized Studies of Interventions.

Discussion

To our knowledge, this is the first thorough review examining the impact of mHealth via WeChat on women. Although mHealth has been widely applied in various fields of obstetrics and gynecology, including prenatal care, postpartum health management, and gynecological disease prevention [60-62], the specific application of WeChat-based mHealth interventions in this population remains underexplored. In the included studies, WeChat-based mHealth was reported to be associated with greater access to personalized health information [63], observed to support self-management capabilities [64], and documented to enable real-time communication with health care providers [65]. This technology suggested beneficial effects on women's proactive engagement in health monitoring and improving overall reproductive health outcomes.

As a popular social media platform in China, WeChat shows promising potential as an mHealth platform. It has been applied to support chronic disease management by providing personalized health guidance and support [63]. People do not need to download software specifically, and all functions are on WeChat, which people use every day. Specifically, WeChat's group chat may help build health support groups and promote interaction and experience sharing among participants [33,66,67]. WeChat's public account provides an effective channel for health education. Through public accounts, health professionals can regularly publish relevant information on health knowledge, disease prevention, and healthy lifestyles. This model was reported to reach large audiences and allow timely updates, with potential links to health literacy [68]. Finally, applets integrate health monitoring tools and personalized health plans, potentially supporting long-term health management and behavior tracking. This personalized intervention can provide customized health advice and support based on users' specific health conditions and needs, thereby improving the effectiveness of health management [66]. Altogether, WeChat, through its diverse functions, provides strong support for the implementation of mHealth, becoming an important tool for promoting health management and health education.

Our findings revealed that the effective implementation of mHealth involved collaboration among multidisciplinary teams. Obstetricians play a central role in assessing and managing the health of pregnant women and adjusting treatment plans. Midwives provide support and care to ensure the safety and comfort of pregnant women [69]. In addition, the involvement of internal medicine physicians is crucial for managing chronic conditions in pregnant women, such as gestational diabetes or hypertension. Dietitians help pregnant women maintain a healthy weight and nutritional status through personalized dietary advice, thereby promoting the health of both mother and baby [31,51]. This multidisciplinary management model may improve the quality of obstetric care and strengthen communication and collaboration among health care providers [70].

The highly cited studies serve as pivotal clinical cornerstones for WeChat-based mHealth interventions in women's health. These landmarks cover breast cancer, perinatal mental disorders, breastfeeding difficulties, and gestational diabetes mellitus. In most cases, these conditions demand continuous and personalized self-management, which conventional outpatient care struggles to fulfill efficiently. Breast cancer patients often face various physiological and psychological challenges during and after treatment, and remote rehabilitation effectively improves patients' mental health and cognitive function [71]. Pregnant women are vulnerable to anxiety and depression and need timely psychological intervention [72]. Breastfeeding is one of the optimal ways for infants to obtain optimal nutrition; however, in practice, many mothers face various challenges. Therefore, sustained health education is crucial for the success of breastfeeding [73]. Meanwhile, women with gestational diabetes depend on regular glucose monitoring, dietary coaching, and behavioral supervision. Collectively, WeChat overcomes the temporal and spatial limitations of traditional care, enabling persistent, tailored, and responsive support.

Most eligible studies were RCTs, and RCTs are widely regarded as the gold standard in evidence-based medical research. Since mHealth interventions delivered via WeChat are difficult to blind in practice, performance bias and detection bias were almost unavoidable in the included trials. However, measurement bias and selective reporting bias are two common issues in these mHealth-related RCTs. Selective reporting bias suggests that researchers may selectively report certain outcomes while omitting or altering others to highlight statistically significant results. In leading journals in dentistry, the incidence

XSL•FO
RenderX

of selective reporting bias is 51.5%, with the most common form being inconsistent assessment times for primary outcomes [74]. Even 85% of trials did not fully adhere to prespecified results in the antipsychotic drugs field [75]. Researchers and policymakers must enhance their understanding of the various assumptions, biases, and limitations to elevate the quality of RCTs. Moreover, RCTs ought to be combined with other research techniques to create a more thorough evidence base [76]. In particular, researchers should use objective, validated tools to measure key outcomes rather than relying solely on subjective self-reported data. For instance, researchers leveraged sensor data from smartphones and smartwatches combined with machine learning algorithms to detect emotional states and transitions [77]. By integrating deep neural networks with visual indicators, the mental health status of cancer patients can be objectively evaluated, achieving a high level of classification accuracy [78]. Only with improved methodological quality can this field establish a robust evidence base and achieve stable, scalable, and trustworthy mHealth models.

Our analysis has some limitations. First, current research mostly focuses on a single cultural context, while under multicultural settings, the effectiveness of WeChat mHealth apps may vary. Culturally adapted behavioral health interventions are more effective in improving health behaviors and outcomes [79]. The process of cultural adaptation is complex and requires multiple stages, including information collection, preliminary design, testing, refinement, and final implementation. Therefore, researchers can explore the adaptability and effectiveness of WeChat mHealth apps in different cultural contexts through cross-cultural comparative studies [80]. Second, despite many studies proving the short-term benefits of WeChat mHealth, conducting long-term follow-up studies can offer a deeper understanding of its enduring impact on health management and how it changes over different periods [81,82]. Third, combining WeChat with other technological platforms (such as wearable devices and electronic health record systems) could further enhance the effectiveness of these interventions [83].

WeChat‐based mHealth interventions show promising but still uncertain potential in improving access to personalized health information, enhancing self-management, and facilitating real-time doctor-patient communication. Given the high risk of bias across most included studies, the overall strength of evidence remains low and does not support definitive effectiveness. Multidisciplinary collaboration is crucial for effective mHealth implementation. Current limitations include a single-cultural context focus and a lack of long-term follow-up. Future studies should adopt more rigorous methodologies, including improved blinding, transparent outcome reporting, and validated objective measures. Cross-cultural adaptability, long-term effectiveness, and integration with wearable technologies should also be examined in subsequent research. This review fills a research gap and provides directions for optimizing WeChat-based mHealth interventions for women.

Abstract

Background: Screen-based 360° contextual simulation videos are increasingly being used in nursing education; however, evidence regarding their effects on learning outcomes and neural electroencephalography (EEG) patterns remains limited.

Objective: This study aims to evaluate whether integrating 360° contextual simulation videos with traditional classroom instruction influences nursing students' perceptions of simulation design and educational practices, their levels of satisfaction and self-confidence in learning, and EEG-based neural correlates of action observation.

Methods: In a quasi-experiment, 55 third-year nursing students (experimental n=28; control n=27) were assigned to 360° contextual simulation video learning (laptop; no head-mounted display) or traditional classroom-based instruction (didactic instruction, guided discussion, and 2D instructional videos). The primary outcomes were Simulation Design Scale (SDS) and Educational Practices Questionnaire (EPQ) scores. Secondary outcomes included Student Satisfaction and Self-Confidence in Learning Scale (SCLS) scores and EEG indices (power at C3, Cz, and C4; μ-rhythm suppression scores). Group differences were tested with 2-tailed *t* tests and analysis of covariance adjusted for baseline values.

Results: Between-group analyses (analysis of covariance adjusted for baseline values) revealed higher posttest scores on the SDS ($F_{1,35}$=7.80, η^2=.182; *P*=.008), EPQ ($F_{1,35}$=6.00, η^2=.146; *P*=.02), and SCLS ($F_{1,35}$=7.01, η^2=.167; *P*=.01) in the experimental group compared to the control group. Within-group analyses (paired *t* tests) indicated significant increases in SDS and EPQ scores for the experimental group (*P*<.001 and *P*=.005), whereas the control group showed a decrease in the SDS score (*P*=.001) and no significant change in the EPQ score (*P*=.11). The SCLS score did not significantly change in the experimental group (*P*=.21) but increased in the control group (*P*=.04). EEG analyses revealed significant postexposure reductions in power at C3, Cz, and C4 for the experimental group (all *P*<.001), with between-group effects at Cz ($F_{1,35}$=425.29, η^2=.926; *P*<.001) and C4 ($F_{1,35}$=5.45, η^2=.138; *P*=.03). μ-Suppression, which is an indirect EEG correlate that is often reported during action observation, was greater in the experimental group at Cz (*P*=.03) and C4 (*P*=.03) but not at C3 (*P*=.13). No adverse events were reported.

Conclusions: Integrating 360° contextual simulation videos into undergraduate nursing education was associated with higher SDS and EPQ scores and improved self-reported satisfaction and self-confidence, in addition to EEG-based findings that may reflect neural EEG patterns associated with action observation. Larger multisite randomized trials are warranted to confirm efficacy and cost-effectiveness.

Introduction

Problem and Rationale

Simulation-based learning has emerged as an essential pedagogical approach in undergraduate nursing education, especially for skill-based disciplines, such as nursing [1,2]. In particular, simulation-based learning has significant value in resource-limited settings where clinical or practical training opportunities may be restricted [1,3]. In undergraduate nursing education, repeated supervised practice is often constrained by limited clinical placements and patient access, limited faculty supervision time, and the limited availability of high-fidelity

XSL•FO
RenderX

simulation facilities. Therefore, simulation-based learning can provide a standardized and safe environment for repeated observation, practice preparation, and feedback to support foundational skill acquisition and clinical decision-making [1-4]. Contextual simulations replicate real-world scenarios in controlled learning environments, thus allowing students to develop critical skills in a safe and structured manner [2]. This approach has been widely recognized for its ability to improve learners' knowledge, skills, and behavioral performance and to support clinical decision-making abilities in health professions education [1,4]. The effectiveness of simulation-based education has been well documented in nursing education and broader health professions education [1,4].

What Is Known About Screen-Based 360° Contextual Simulation Videos

Screen-based 360° contextual simulation videos (laptop, no head-mounted display) can provide standardized exposure to nursing procedures and clinical contexts while allowing learners to control their viewing direction during action observation, which is particularly relevant for early-stage skill acquisition and preparation before supervised practice [5,6]. With recent advancements in more immersive panoramic viewing experience learning technologies, screen-based 360° contextual simulation videos have been identified as innovative alternatives to conventional instructional methods across undergraduate nursing education contexts [5,6]. Recent systematic reviews and meta-analyses have also supported the effectiveness of immersive virtual reality in nursing education for improving learners' knowledge, skills, and problem-solving abilities [7]. Unlike standard fixed-view videos, our screen-based 360° contextual simulation video system allowed learners to actively control their viewing direction while observing context-rich clinical procedures on a laptop screen without a head-mounted display [5,6].

Knowledge Gap

Despite the increasingly widespread adoption of screen-based 360° contextual simulation videos in undergraduate nursing skills training, empirical evidence remains limited, particularly in resource-limited educational settings where supervised practice opportunities are constrained by limitations with respect to clinical patient access, faculty time, and access to high-fidelity simulation facilities [3]. In this context, evidence of the efficacy of screen-based 360° contextual simulation videos—especially regarding observational learning during procedural skill observation and associated electroencephalography (EEG)-based indices during action observation (eg, μ-rhythm suppression)—remains sparse [6,8]. Existing studies have rarely examined both (1) learners' perceptions of simulation quality and educational practices and (2) learners' satisfaction and self-confidence alongside EEG-based indices during action observation [6]. Clarifying these outcomes together may help educators understand not only how students perceive screen-based 360° contextual simulation videos but also how such exposure relates to EEG patterns that are commonly reported during procedural observation. However, our understanding of the direct impact of screen-based 360° contextual simulation videos on cognitive and neural mechanisms, particularly with respect to skill acquisition, learning retention, and neurophysiological engagement, remains limited [6,9]. In addition, the use of EEG to analyze neural correlates in contexts involving screen-based 360° contextual simulation video learning remains relatively underexplored [9]. Accordingly, this study addresses this gap using a 2-group comparison to examine students' perceived simulation design and educational practices, satisfaction and self-confidence in learning, and sensorimotor EEG indices during procedural action observation in response to a screen-based 360° contextual simulation video intervention. Furthermore, investigations into how these simulations influence neural engagement, particularly through observational learning processes, have been limited.

Study Justification and Aim

Mirror neuron theory proposes that observing others' actions can engage the neural systems involved in action execution, supporting observational learning [10]. In EEG research, μ-rhythm suppression over sensorimotor regions is commonly reported during action observation and is often interpreted as an indirect neural correlate that is consistent with mirror neuron system engagement; however, it is not a direct measure of mirror neuron EEG patterns [8,11]. This framework offers a plausible neurophysiological explanation, suggesting that observing tasks in contextual settings stimulates neural circuits that are associated with action execution and cognitive processing and may support motor skill acquisition and memory retention [8,10]. Specifically, EEG studies have identified μ-rhythm suppression as an indirect marker that is consistent with mirror neuron system engagement in the context of observational learning within immersive environments [8,11]. The Kolb experiential learning framework was used as a guiding lens through which to interpret how video-based exposure and facilitated reflection may support early phases of skill learning in undergraduate nursing education [12]. Additionally, recent neuroeducation research suggests that observational learning in immersive media may engage the mirror neuron system, as indexed by EEG μ-rhythm suppression [8,11]. Furthermore, cognitive load theory provides a useful design lens for screen-based simulation by emphasizing strategies that reduce extraneous load and support meaningful processing during procedural learning [13].

To our knowledge, few studies have directly integrated EEG-based learning analytics with screen-based 360° contextual simulation videos in undergraduate education. As multimodal learner data—including biometric signals—are increasingly leveraged in artificial intelligence–enhanced learning analytics to enable real-time feedback and personalization, understanding how immersive simulations influence neural engagement is important for informing adaptive educational models [14]. The aim of this study was to evaluate the effects of screen-based 360° contextual simulation videos on undergraduate nursing students' (1) perceived simulation design and educational practices, (2) satisfaction and self-confidence in learning, and (3) sensorimotor EEG indices during procedural action observation (sensorimotor power and μ-rhythm suppression) by comparing an experimental group with a control group using questionnaires and EEG measures. The screen-based 360° contextual simulation videos were delivered on a laptop screen

XSL•FO
RenderX

without a head-mounted display; therefore, the intervention is distinct from headset-based virtual reality simulation.

Methods

Design

This study had a 2-group, pretest-posttest quasi-experimental design with 2 assessment time points. The participants were assigned to either an experimental group or a control group using a computer-generated allocation sequence. However, because recruitment was convenience-based within a single university cohort and blinding was not implemented, the study is reported as quasi-experimental. The reporting of this study was guided by the CONSORT (Consolidated Standards of Reporting Trials) 2010 checklist, where applicable (Checklist 1).

Setting and Participants

Participants were recruited through announcements made in undergraduate courses and departmental emails within a university setting, and a nursing cohort was used as the case sample. An a priori power analysis was conducted using G*Power to estimate the minimum sample size planned for an analysis of covariance (ANCOVA) framework (2 groups, 1 covariate), assuming a medium effect size (f=0.25) in the absence of robust preliminary data, with α=.05 and power=0.80, yielding a minimum required sample of 34. The inclusion criteria for this study were as follows: (1) being a third-year undergraduate student in a nursing program, (2) being able to converse in Taiwanese and Mandarin, and (3) being willing to participate voluntarily in the research. The exclusion criteria were deafness or cognitive impairment according to various sources (such as school health information and parental notification). The participants were assigned to either the experimental group (screen-based 360° contextual simulation video learning) or the control group (dose-matched screen-based 2D instructional video learning), with the video learning conducted during after-class skills practice sessions.

Procedures

The study was conducted over 1 week in July 2024 and included 2 assessment time points: baseline (T0) and immediately postintervention (T1). On day 1, all participants completed baseline questionnaires and underwent baseline EEG recording. Pretest EEG recording was conducted in the eyes-open resting condition and did not involve viewing any simulation content or videos. After the baseline assessment, the participants were allocated to either the experimental or control group. Both groups completed 4 learning modules within the week. Each module followed the same overall structure in both groups: a brief orientation, video viewing on a laptop (approximately 10 - 12 min), and a 20-minute instructor-facilitated discussion using structured prompts; each module was designed to be completed within approximately 60 minutes. Immediately after the final module, posttest questionnaires were administered and collected under standardized proctoring by faculty members and teaching assistants, and the participants underwent posttest EEG recording. This procedure was identical for the control group; the posttest EEG data were recorded immediately after the fourth control module in the same eyes-open resting condition.

Theoretical Framework

As noted in the *Introduction* section, the Kolb experiential learning cycle informed the design and interpretation of the intervention; the operationalization of each stage in this study is described below. Concrete experience was operationalized as students' exposure to screen-based 360° procedural scenarios. Reflective observation was supported through structured, instructor-guided debriefing immediately after viewing. Abstract conceptualization was supported by linking the observed actions to key procedural principles and checklists during the discussion and through assigned review materials. Active experimentation was operationalized as students' subsequent application of the observed steps during routine skills practice (outside the 360° viewing session) using the same procedural checklist and course materials [12].

Interventions

The study included 2 intervention conditions delivered via the university's institutional eLearning platform and accessed through a standard web browser on laptop computers. The 4 modules covered (1) the collection of urine specimens from a urine drainage bag, (2) the measurement and documentation of vital signs, (3) infant and pediatric cardiopulmonary resuscitation, and (4) chest physiotherapy. The modules were matched by topic and intended duration across groups and were completed during after-class skills practice sessions within the 1-week study period.

Experimental Condition: Screen-Based 360° Contextual Simulation Videos

The experimental intervention consisted of screen-based 360° contextual simulation video learning delivered on laptop computers without a head-mounted display. In this study, "immersion" refers to panoramic 360° first-person viewing of realistic clinical procedures with context-rich audiovisual cues, and "interactivity" refers to learners' ability to actively control their viewing direction (through panning and rotating) during observation. Because the videos were presented on a laptop screen, the level of immersion and interaction was lower than that of fully immersive headset-based virtual reality. All screen-based 360° contextual simulation videos were self-developed by the nursing faculty and information engineering professionals through interdisciplinary discussions and were delivered via the institutional eLearning platform. Before each module, the students received a brief orientation that included learning objectives, instructions on how to navigate the 360° video (eg, how to change viewing direction), and expectations for participation. Each module included viewing of the corresponding screen-based 360° contextual simulation video (approximately 10 - 12 min), followed by a 20-minute facilitated contextual debriefing led by faculty members using structured prompts focused on key steps, safety considerations, and clinical decision-making. Each module was designed to be completed within approximately 60 minutes and focused on a single, discrete nursing skill. The participants had no prior

XSL•FO
RenderX

exposure to the 4 study-specific 360° modules before baseline assessment.

Control Condition: Dose-Matched 2D Instructional Videos

The control group covered the same 4 skill topics and used dose-matched, screen-based 2D instructional videos and the same overall module structure and scheduling. The 2D instructional videos were developed by the same teaching team and delivered through the same institutional eLearning platform accessed on a laptop via a web browser. Before each module, the students received a brief orientation that included learning objectives, instructions on how to access and view the 2D video (fixed-view, with no panning or rotation control), and expectations for participation. The educational content included (1) didactic instruction and demonstration of key procedural steps, (2) viewing of the corresponding 2D instructional video (approximately 10‐12 min), and (3) a 20-minute instructor-facilitated discussion using the same structured prompts as the experimental condition (key steps, safety considerations, and clinical decision-making). Each module was designed to be completed within approximately 60 minutes and was matched to the experimental condition by topic and duration. The control activities did not involve high-fidelity mannequin simulation, standardized-patient scenarios, or 360° video viewing.

Instructional Design and Standardization (Cognitive Load-Informed Features)

The intervention was designed with cognitive load theory–informed considerations to minimize extraneous demands and support learning efficiency. Across both conditions, each video was kept short (approximately 10‐12 min) and focused on a single skill topic. Key procedural steps were standardized using step-by-step procedural checklists reinforced during the instructor-guided discussion, and the learning environment and delivery platform were kept consistent across groups. We did not directly measure cognitive load; therefore, these elements are reported as design features rather than demonstrated mechanisms. Accordingly, unmeasured cognitive load and related factors (eg, attention or fatigue) may have influenced EEG indices and learning outcomes, which should be interpreted cautiously.

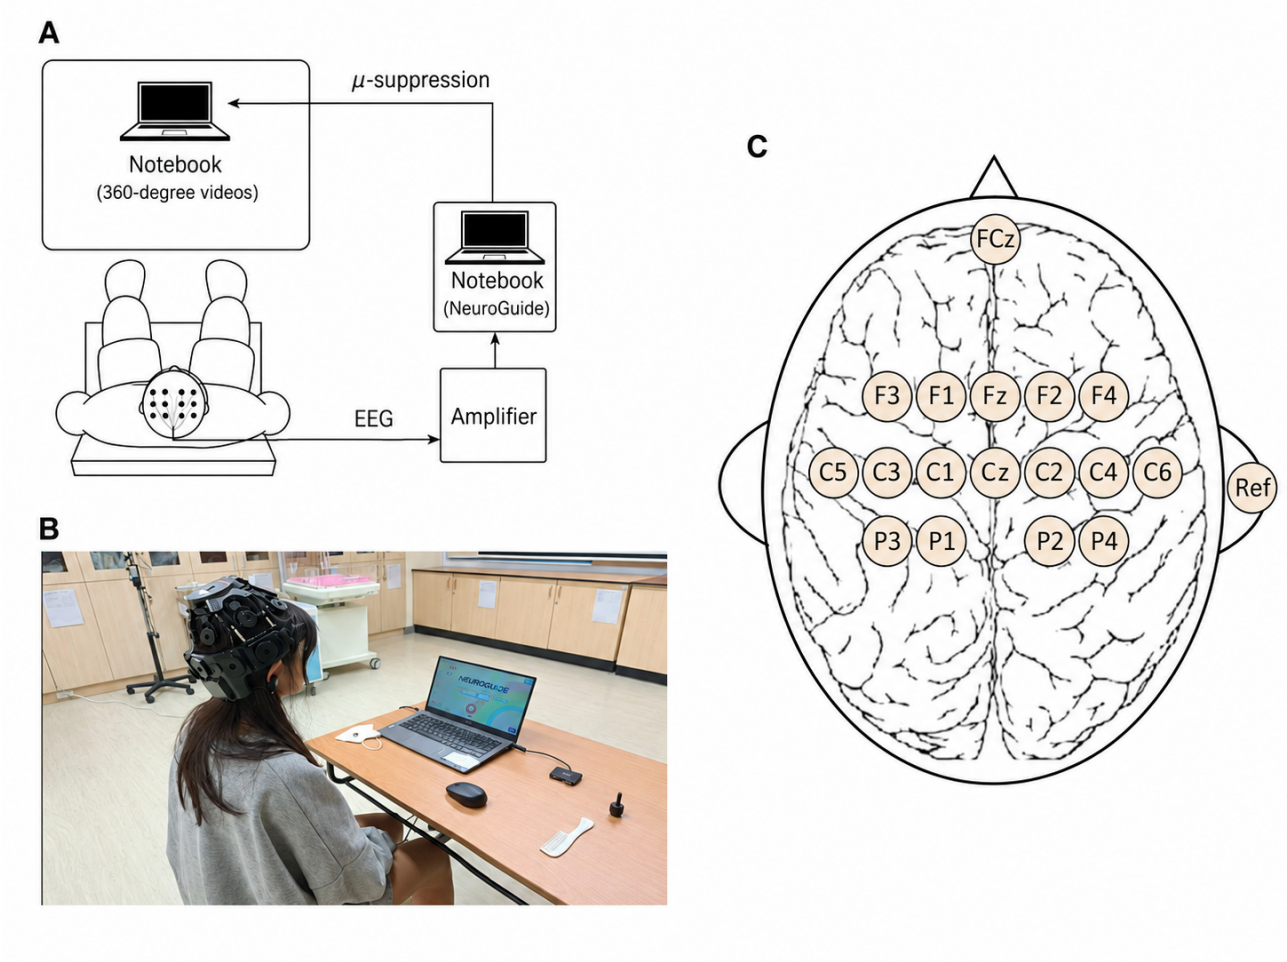
Questionnaire Measures

Quantitative data were collected via 1 demographic questionnaire and 3 additional questionnaires, and perceptions of simulation design and educational practices were assessed using the Simulation Design Scale (SDS) and the Educational Practices Questionnaire (EPQ), respectively. Satisfaction and self-confidence in learning were assessed using the Student Satisfaction and Self-Confidence in Learning Scale (SCLS). All of these instruments are contextual simulation research questionnaires developed by the National League for Nursing [15]. The reliability of the questionnaires was evaluated according to Cronbach α coefficient. Experts have recommended the use of these measurement questionnaires when implementing contextual simulations in education programs [15].

The SDS is composed of 20 items and is used to assess students' views concerning design elements pertaining to simulation and their importance. The questions address course themes and knowledge, support, problem-solving, feedback, and simulation contexts. In terms of reliability, the Cronbach α coefficient for the overall SDS was 0.96. The α coefficients for the knowledge of course themes, support, problem-solving, feedback, and simulation context scales were 0.92, 0.92, 0.86, 0.90, and 0.87, respectively. In terms of validity, the root mean square error of approximation (RMSEA), normed fit index (NFI), weighted root mean square residual (WRMR), and chi-square significance tests indicated a poor fit, whereas the comparative fit index (CFI), Tucker-Lewis index (TLI), and adjusted goodness-of-fit index (AGFI) values were greater than the commonly accepted thresholds. The conceptual model accounted for 17 out of 20 SDS items (85%). The correlations between different pairs of theoretical factors ranged between 0.67 and 0.89 [16].

The EPQ comprises 16 questions and is used to evaluate students' views concerning the importance of using simulations in virtual environments in educational practice. The responses are scored on a 5-point Likert-type scale. These 16 items cover various subscales, including active learning, cooperation, varied learning styles, and high expectations. In terms of reliability, the Cronbach α coefficient for the overall EPQ was 0.95. The α coefficients for the active learning, cooperation, diversified learning style, and high expectation subscales were 0.93, 0.90, 0.88, and 0.88, respectively. In terms of validity, the RMSEA, WRMR, and chi-square significance tests indicated that the fit was not good, whereas the CFI, TLI, NFI, and AGFI values were greater than the commonly acceptable thresholds. The conceptual model accounted for 13 out of 16 EPQ items (approximately 80%). The correlations between different pairs of conceptual factors ranged between 0.77 and 0.86 [16].

The SCLS comprises 14 items and is used to measure participants' satisfaction with and confidence in the current learning protocol on a 5-point Likert-type scale. In terms of reliability, the Cronbach α coefficient for the entire SCLS was 0.92, and the α coefficients for the satisfaction and confidence subscales were 0.92 and 0.83, respectively. In terms of validity, the RMSEA, WRMR, and chi-square significance tests indicated that the degree of fit was not good, whereas the CFI, TLI, NFI, and AGFI values were greater than the commonly accepted thresholds. The conceptual model accounted for 11 out of 14 (approximately 76%) SCLS items. The correlation coefficient between the satisfaction and confidence factors was 0.78 [16].



EEG Measures

EEG recordings were obtained in a quiet room with the participants seated comfortably in front of a laptop screen. Electrode impedances were checked before each recording and maintained below the manufacturer-recommended threshold throughout the session. The baseline EEG (T0) data were recorded under standardized resting conditions prior to any module exposure, and the postintervention EEG (T1) data were recorded immediately after the completion of the module under the same recording setup. The same acquisition settings and recording environment were used for both groups to ensure comparability across time points and conditions. After the EEG

XSL•FO
RenderX

recordings were obtained, the EEG data were analyzed by a professional pediatric neurologist based on a standardized protocol. The EEG system consisted of both hardware (DSI-24 EEG headset; Wearable Sensing) and software (NeuroGuide version 3.4.0; Applied Neuroscience, Inc.). The EEG data were collected with the assistance of a Neuroscan SynAmps system with a 0.1 - to 30-Hz bandpass filter and a sampling rate of 500 Hz. For analysis, we extracted the first 160 seconds of eyes-open EEG data from each recording. The participants did not perform an active task during this segment (Figure 1). The μ waves were defined as the oscillations measured in the sensorimotor cortex; therefore, only the data obtained from C3, Cz, and C4 were analyzed. The EEG data were analyzed with the assistance of MATLAB and EEGLAB. The fast Fourier transform was applied with a Hanning window, and the power spectral density was computed for each 2-second epoch [17] (details are provided in Multimedia Appendix 1).

Figure 1. Schematic representation of the experimental setup for electroencephalography (EEG)-based analysis in pediatric nursing training (**A**), a participant using the screen-based 360° contextual simulation video system with EEG recording (**B**), and electrode placement for EEG data acquisition (**C**).

Statistical Analysis

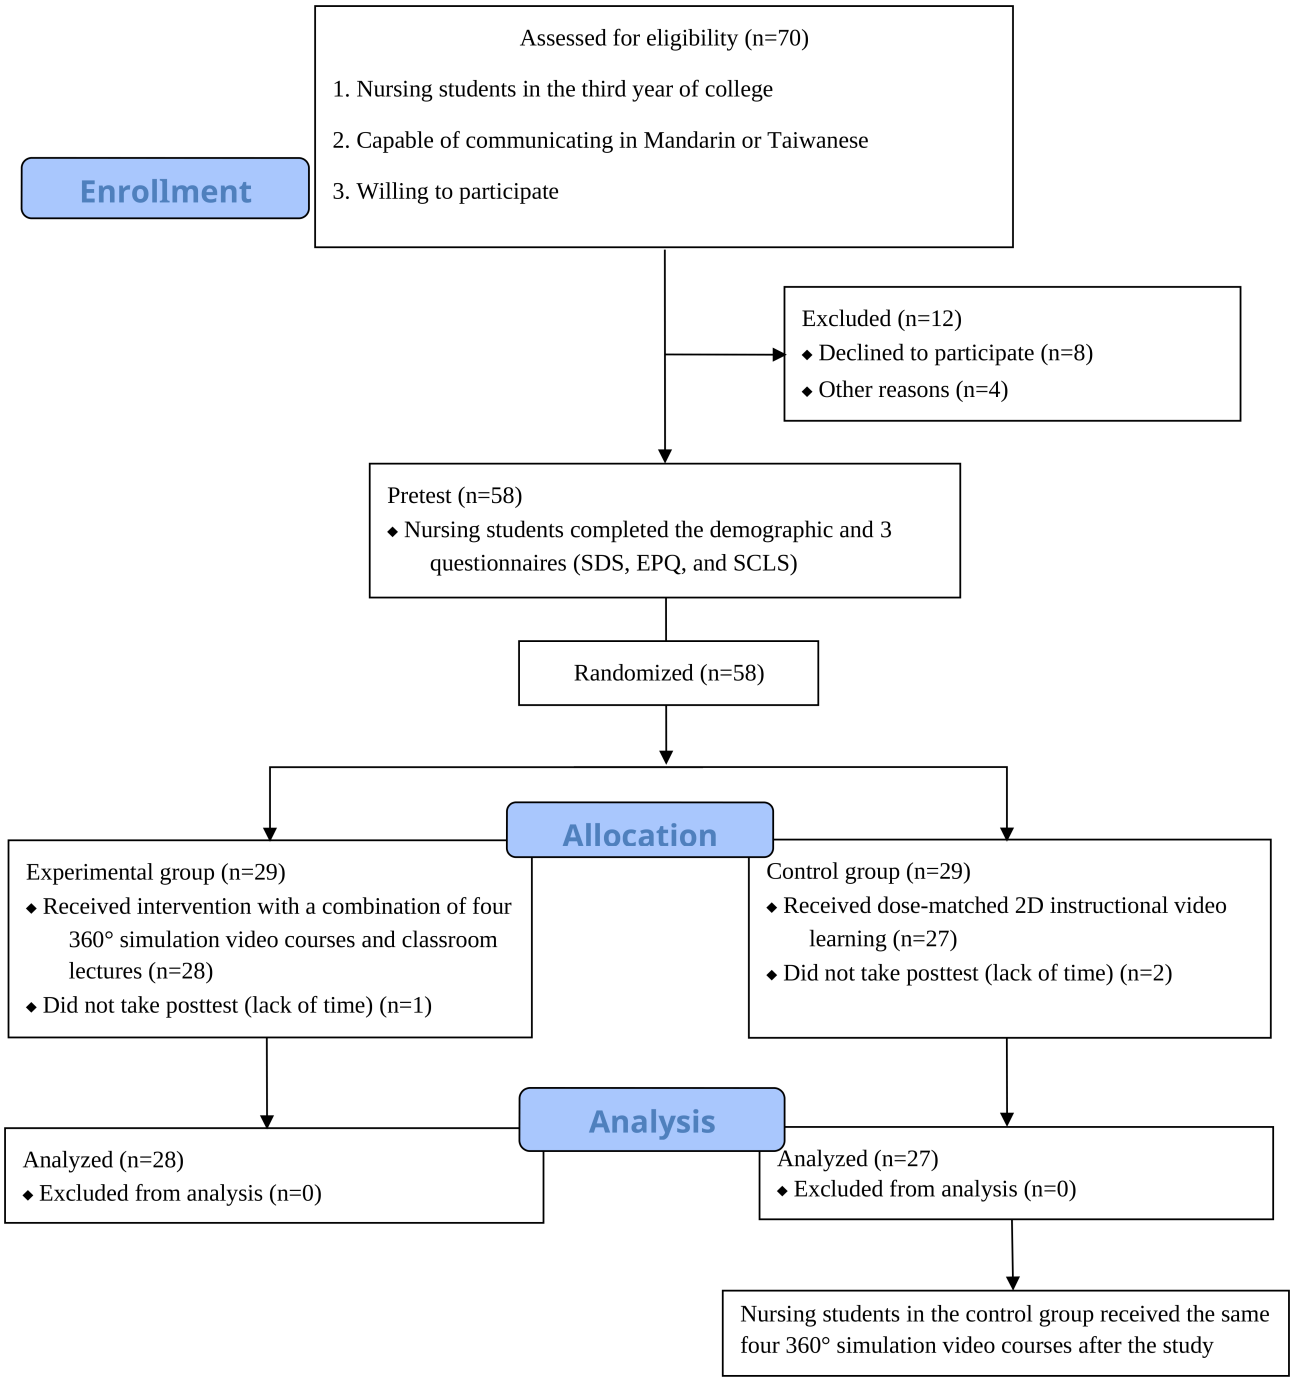
Missing questionnaire data were handled using a prespecified rule. The SDS, EPQ, and SCLS comprise 50 (20+16+14) items in total. Questionnaire records with ≥10 missing items at a given assessment time point were excluded from the questionnaire-based analyses because this level represents ≥20% missingness, a level at which scale scores may be unstable. All questionnaire- and EEG-derived outcomes were analyzed by an analyst who was not involved in intervention delivery or questionnaire administration [18] using IBM SPSS Statistics (version 25). Descriptive statistics are reported as the means (SDs). All statistical tests were 2-tailed, and statistical significance was set at $P<.05$. For the questionnaire outcomes, Pearson correlation coefficients were calculated to examine the associations between the pretest and posttest scores within each group. The analyses of the SDS and EPQ scores were treated as primary, whereas those of the SCLS scores and EEG indices were treated as secondary. Within-group pretest-to-posttest changes were evaluated using 2-tailed paired-samples *t* tests for each questionnaire outcome. Between-group differences in questionnaire outcomes were examined using ANCOVA, with the posttest score as the dependent variable, the group as the fixed factor, and the baseline (pretest) score as the covariate. Assumptions were assessed using Levene tests for homogeneity of variances and by testing the interaction between the group and baseline scores to evaluate the homogeneity of regression slopes. Effect sizes are reported as partial η^2 [19]. For EEG power measures at C3, Cz, and C4, Pearson correlation coefficients were calculated to examine the associations between the pretest and posttest values within each group. Within-group pretest-to-posttest changes in EEG power were evaluated using

XSL•FO
RenderX

2-tailed paired-samples *t* tests at each electrode site. Between-group differences in EEG power were assessed using Levene tests for homogeneity of variances and tests of the group × baseline interaction to evaluate the homogeneity of regression slopes. When the assumption of homogeneity of regression slopes was met, ANCOVA was conducted with the posttest EEG value as the dependent variable, the group as the fixed factor, and the baseline EEG value as the covariate. When the assumption was violated, ANCOVA was not performed for that electrode. Effect sizes are reported as partial η^2 [19]. Between-group differences in the μ-suppression scores at C3, Cz, and C4 were examined using 2-tailed independent-samples *t* tests. Levene tests were used to assess the homogeneity of variances prior to each *t* test.

Ethical Considerations

The study protocol was conducted in accordance with institutional and national research ethics standards and the Declaration of Helsinki and approved by the Institutional Review Board of the MacKay Memorial Hospital, Taiwan (No. 21MMHIS438e). Informed consent was obtained from all participants. The participants were provided with a consent form on day 1 before baseline (T0), and consent was obtained immediately prior to administering the baseline questionnaires and conducting EEG recording. No participants withdrew after providing their consent. Participant privacy and confidentiality were protected throughout the study. All questionnaire and EEG data were coded and deidentified before analysis, and no names, student identification numbers, or other directly identifying information were included in the analytic dataset. Research data were stored in password-protected files and were accessible only to authorized members of the research team. The findings are reported in aggregate form only. Participants each received NT $300 (US $9.5) as compensation for their time. A detailed study protocol is provided in Multimedia Appendix 2.



Results

Participants

No questionnaire records were excluded at baseline (T0). At posttest (T1), 3 questionnaire records were excluded because of ≥10 missing items (1 in the experimental group and 2 in the control group). A total of 55 out of 70 students (79%), including 28 students in the experimental group and 27 students in the control group, completed both the pretest and posttest assessments. The CONSORT flow diagram, which outlines the participant recruitment and retention process used in this study, is shown in Figure 2. Baseline demographic characteristics and pretest outcome measures were comparable between the experimental and control groups, as shown in Table 1.

Effect of Screen-Based 360° Contextual Simulation Videos on Questionnaire Measures

Within-Group Analyses

In the experimental group, the correlation coefficients between the pretest and posttest scores for the SDS, EPQ, and SCLS were 0.258, −0.006, and −0.145, respectively. Two-tailed paired-sample *t* tests revealed statistically significant increases in the SDS (t_{27}=−6.44; *P*<.001) and EPQ (t_{27}=−3.47; *P*=.005) scores, whereas the changes observed in the SCLS scores were not statistically significant (t_{27}=−1.32; *P*=.21; Table 2).

P_3 and η^2 were calculated by analysis of covariance to compare the posttest scores between the groups, and adjustments were made for baseline differences.

[f]C3, Cz, and C4: EEG electrode placement locations based on the international 10-20 system.

[g]Not applicable.

In the control group, the correlation coefficients between the pretest and posttest scores for the SDS, EPQ, and SCLS were −0.192, 0.435, and 0.323, respectively. Two-tailed paired-samples *t* tests indicated a statistically significant

XSL•FO
RenderX

decrease in the SDS score (t_{26}=−5.50; *P*=.001) and a statistically significant increase in the SCLS score (t_{26}=−2.13; *P*=.04), whereas the change in the EPQ score (t_{26}=−1.67; *P*=.11) was not statistically significant (Table 2).

Between-Group Analyses

The assumptions for ANCOVA were checked (homogeneity of variances and homogeneity of regression slopes) and were met for the SDS, EPQ, and SCLS scores (details are provided in Multimedia Appendix 3). ANCOVA revealed significant between-group effects for the SDS, EPQ, and SCLS scores (Table 2), indicating that exposure to the screen-based 360° contextual simulation videos significantly influenced these questionnaire outcomes. Effect sizes (partial η^2) are reported in Table 2. Taken together, the results indicate that, relative to the dose-matched control condition, the 360° video condition was associated with more favorable posttest student-reported perceptions of simulation design and educational practices (SDS and EPQ) and higher satisfaction or self-confidence (SCLS) after adjusting for baseline scores.

Effects of Screen-Based 360° Contextual Simulation Videos on EEG Measures

Within-Group Analyses

In the experimental group, the correlation coefficients between the pretest and posttest values at electrode sites C3, Cz, and C4 were 0.550, 0.999, and 0.873, respectively. Two-tailed paired-sample *t* tests revealed statistically significant reductions in EEG power frequencies at all 3 electrode sites: C3 (t_{27}=3.93; *P*<.001), Cz (t_{27}=5.41; *P*<.001), and C4 (t_{27}=4.82; *P*<.001). These findings indicate a significant decrease in EEG power frequencies after exposure to the screen-based 360° contextual simulation videos.

In the control group, the mean (SD) pretest and posttest EEG power frequencies at C3, Cz, and C4 were 13.47 (SD 11.85) Hz versus 11.50 (SD 9.59) Hz, 71.20 (SD 187.27) Hz versus 66.28 (SD 183.41) Hz, and 15.84 (SD 17.76) Hz versus 13.39 (SD 12.08) Hz, respectively. The correlation coefficients between the pretest and posttest values at C3, Cz, and C4 were 0.953, 0.999, and 0.803, respectively. Two-tailed paired-sample *t* tests for the control group yielded the following results: C3 (t_{26}=1.79; *P*=.10), Cz (t_{26}=2.05; *P*=.06), and C4 (t_{26}=0.85; *P*=.41; Table 2). None of these *P* values reached statistical significance, thus indicating no significant changes in EEG power frequencies at any of the 3 electrode sites among participants who did not engage with the screen-based 360° contextual simulation videos.

Between-Group Analyses

The assumptions for between-group comparisons were assessed (details are provided in Multimedia Appendix 3). For the EEG power outcomes, the assumption of homogeneity of regression slopes was violated for C3; therefore, ANCOVA was not performed for C3. The ANCOVA results for Cz and C4 indicated significant between-group differences in posttest eyes-open resting-state EEG power after adjusting for baseline values (Table 2). Two-tailed independent-samples *t* tests revealed significant between-group differences in μSC at Cz and C4 (Table 3). In this study, μSC reflects eyes-open resting-state μ-band modulation rather than task-evoked suppression. These results indicate between-group differences in posttest resting-state μ-band indices at selected sites.

Table . Effects of the screen-based 360° contextual simulation videos on the μ-suppression scores between groups (n=55).

Variable μSC[a]	*t* test (df)	*P* value	Mean difference	SE difference	95% CI
C3	1.57 (53)	.13	16.89	10.77	−4.93 to 38.72
Cz	2.29 (53)	.03[b]	22.45	9.80	2.59 to 42.30
C4	2.21 (53)	.03[b]	23.69	10.71	1.20 to 45.38

[a]μSC: μ-band indices derived from eyes-open resting electroencephalography.

[b]*P*<.05. *P* values were calculated by performing 2-tailed independent samples *t* tests to examine the differences between groups.

Discussion

Principal Findings

This study revealed that exposure to screen-based 360° contextual simulation videos was associated with significant changes in both questionnaire outcomes and resting-state EEG indices. In the within-group analyses, the experimental group showed significant pretest-to-posttest improvements in SDS and EPQ scores and significant reductions in EEG power at C3, Cz, and C4, whereas the control group showed limited or nonsignificant changes in most measures. In between-group analyses, ANCOVA indicated that significant group effects for SDS, EPQ, and SCLS and resting-state EEG outcomes also differed between groups at selected electrode sites (Cz and C4), with additional between-group differences observed in the μ-rhythm indices at Cz and C4.

Key Considerations

The findings indicate that the students positively responded to the use of screen-based 360° contextual simulation videos, reporting high levels of satisfaction with instructional design and teaching methodologies. These findings suggest that, compared with the control condition, exposure to screen-based 360° contextual simulation videos was associated with more favorable student-reported perceptions of simulation design and educational practices (SDS and EPQ scores) and higher self-reported satisfaction and self-confidence (SCLS scores). Additionally, the resting-state EEG indices (eyes-open) showed pre-post changes in the experimental condition, and group differences were observed at selected sensorimotor sites (eg, Cz and C4; Table 2). Because EEG data were collected in the eyes-open resting condition rather than during video viewing, these findings should be interpreted as overall pre-post

XSL•FO
RenderX

sensorimotor rhythm modulation following learning exposure, not as direct video format-evoked action-observation responses. From an educational perspective, the use of screen-based 360° contextual simulation videos may represent a scalable approach to support procedural action observation in health professions training [5,6]. However, motor learning and cognitive engagement were not directly measured in this study and should be examined using objective performance outcomes and broader cognitive measures in future work.

EEG analyses indicated significant pre-post modulation of sensorimotor rhythm power at C3, Cz, and C4 in the eyes-open resting condition, with group differences at selected sites (eg, Cz and C4). Because EEG data were recorded in the eyes-open resting state at T0 and T1, these results reflect overall pre-post changes following exposure to the respective learning conditions rather than neural responses elicited during video viewing. Because the EEG analyses in this study focused on central sensorimotor sites (C3, Cz, and C4), we cannot attribute the observed effects to prefrontal regions or hemispheric dominance. In addition, μ-rhythm suppression is an indirect and nonspecific marker that can be influenced by attention, visual processing demands, and cognitive load. Therefore, these findings should be interpreted as EEG correlates consistent with sensorimotor rhythm modulation rather than as direct evidence of mirror neuron activation, cognitive engagement, or motor learning [8,11]. In future studies, EEG data should be recorded during video viewing under both conditions to examine whether the video format is associated with task-evoked sensorimotor EEG differences during procedural observation.

Taken together, the combination of higher posttest questionnaire scores (SDS, EPQ, and SCLS) and distinct sensorimotor EEG modulation (Cz, C4 power changes, and μ-rhythm indices) suggests that the screen-based 360° contextual simulation video condition was associated with more favorable learner perceptions and with pre-post modulation of resting sensorimotor EEG indices at selected sites. However, EEG data have limited spatial resolution, and μ-suppression is nonspecific [8]; due to the design of this study, specific neural generators could not be isolated, and the potential contributions of attention, visual processing, or unmeasured cognitive load could not be disentangled. Objective technical performance and longer-term retention were not assessed in this study and should be considered in future trials. Beyond EEG outcomes, students in the 360° video condition reported more favorable perceptions of simulation design and educational practices (SDS and EPQ scores) and higher satisfaction or self-confidence (SCLS scores) than did students in the control condition. These self-reported findings support the acceptability of screen-based 360° contextual simulation video learning as a supplement to undergraduate nursing skills education.

In interpreting these findings, Kolb [12] experiential learning cycle provides a useful lens, but the present intervention should be viewed as partially aligned with the model. The screen-based 360° contextual simulation videos primarily supported concrete experience (exposure to realistic procedural scenarios) and reflective observation (facilitated debriefing), and the linked procedural checklists may have supported abstract conceptualization. Consistent with evidence that observing clinical procedures can support skill retention [21], the intervention may help scaffold the early phases of learning. However, active experimentation (hands-on practice with feedback) was not implemented or objectively measured within the study sessions; thus, a complete experiential learning cycle cannot be claimed. In future work, hands-on performance should be integrated and assessed to operationalize active experimentation and retention more directly [22].

Research Implications and Future Directions

From an educational perspective, screen-based 360° contextual simulation videos may offer a scalable supplement for undergraduate nursing skills education, particularly when supervised practice opportunities are constrained. In this study, the 360° video condition was associated with more favorable student-reported perceptions of simulation design and educational practices (SDS and EPQ scores) and higher satisfaction or self-confidence (SCLS scores), along with pre-post modulation of resting sensorimotor EEG indices at selected sites. These EEG findings should be interpreted as indirect, nonspecific neural correlates that are consistent with sensorimotor rhythm modulation rather than as direct evidence of mirror neuron activation, cognitive engagement, motor learning, or clinical competence [8,11]. In future studies, objective performance outcomes (eg, skills checklists), longer-term follow-up, and direct measures of cognitive load should be evaluated, and blended designs that integrate video-based observation with structured hands-on practice and feedback should be incorporated [23].

Limitations

This study was conducted within an academic setting, which may have introduced an inherent power dynamic between the researchers and the participants. The presence of course instructors during data collection could have unintentionally influenced the students' responses to the questionnaires, thereby introducing potential response bias and affecting the reliability of the self-reported measures. Additionally, the relatively small sample size and single-institution design may have limited the statistical power and generalizability of the findings, particularly in the context of diverse higher education environments. Because EEG data were collected in the eyes-open resting condition at T0 and T1 (and not during video viewing), the study could not test whether different video formats directly elicit different action-observation EEG responses. Because all participants completed the 4 modules in a fixed order and EEG data were collected only at baseline and immediately after the final (fourth) module, the EEG findings reflect an overall pre-post change across the full sequence rather than scenario-specific effects. Potential cumulative effects (eg, learning, fatigue, or changes in cognitive load) across the 4 modules cannot be disentangled. In addition, cognitive load was not directly measured, which limits the interpretability of the EEG indices. Although standardized proctoring procedures were used and confidentiality was emphasized, the presence of faculty members and teaching assistants during questionnaire completion may still have introduced social desirability or response bias, which may have affected the validity of the self-reported outcomes. Excluding questionnaire records with substantial missingness

XSL•FO
RenderX

may have introduced response bias if missingness was not random (eg, systematic skipping among less engaged students). Although the number of excluded posttest records was small (3 records at T1), the questionnaire findings should be interpreted with caution in light of potential nonrandom missingness.

Conclusions

This study suggests that integrating screen-based 360° contextual simulation videos into undergraduate nursing education is associated with improved learner-reported outcomes (SDS, EPQ, and SCLS scores) and modulation of eyes-open resting-state sensorimotor EEG indices. Future research should include analyses of objective performance outcomes and task-evoked EEG during video viewing to clarify relevant format-specific mechanisms.

Acknowledgments

The authors sincerely thank all the participants for contributing their time and effort to this study. During manuscript revision and copyediting, the authors made limited use of ChatGPT by OpenAI for minor editorial assistance, including formatting responses to copyeditor queries, and checking consistency with journal style requirements. The tool was not used to generate study data, conduct statistical analyses, interpret results, or create references. All artificial intelligence–assisted content was reviewed, revised, and verified by the authors, who take full responsibility for the accuracy, originality, and integrity of the manuscript.

Funding

This work was supported by the Ministry of Science and Technology, Taiwan (MOST 111 - 2635-H-715-001; NSTC 112 - 2410-H-715-005). Abstract

Background: With the rapid development of generative artificial intelligence (AI) and its deep integration into nursing education, nursing students' AI literacy (AS) has become a critical competency for their professional development. However, the patterns of associations among emotional intelligence (EI), AI self-efficacy (AILS), and AS in relation to comprehensive AS remain unclear.

Objective: Based on the NUR.S.E.S. framework and using network analysis methods, this study systematically mapped the complex relational network among EI, AILS, and AS among undergraduate nursing students. It identified nodes with high centrality and bridging strength within this network, offering preliminary insights that may inform future educational interventions.

Methods: A cross-sectional survey design was used, with 982 undergraduate nursing students from a university conveniently sampled in September 2025 as research participants. Assessments were conducted using the EI Scale, the AILS Scale, and the AS Scale. Using R (version 4.5.1; R Core Team), we constructed a Gaussian graph model, calculated centrality metrics such as node and bridge strength, and assessed network stability using the bootstrap method.

Results: Network analysis showed that emotion regulation (strength centrality=1.355) and evaluative ability (strength centrality=1.323) showed the highest strength centrality, indicating their prominent positions within the network. Emotional perception (bridge strength=0.427) and comfort with AI (bridge strength=0.242) are the most critical bridge nodes, appearing to connect EI with AI technology systems. Simultaneously, the network architecture suggests that AILS may play a bridging role, effectively linking EI (particularly emotional perception as a bridging factor) with higher levels of AS.

Conclusions: Cultivating AS among undergraduate nursing students is a system that deeply integrates emotional, cognitive, and technical confidence. EI was closely associated with AS, and AILS appeared to occupy a bridging position in the network. Educational interventions might consider enhancing emotional perception and comfort with AI, pending validation through longitudinal or experimental designs.

Introduction

The rapid advancement of digital health care technologies, particularly the rise of generative artificial intelligence (GenAI) represented by large language models, is profoundly reshaping the practice paradigms and knowledge boundaries within health care [1]. For nursing students who will become the backbone of the future health care system, this represents both an unprecedented opportunity and a formidable challenge to their capabilities [2]. GenAI can be broadly defined as a subset of artificial intelligence (AI) that focuses on creating new, original, human-like content based on the data it is trained on [3]. A 2024 survey by the Digital Education Council reveals that as many as 85% of students frequently use GenAI in their academic work, with ChatGPT (OpenAI) being the most widely adopted platform among them [4]. Another global survey conducted in 2025 across 109 countries, which collected 20,000 responses, similarly indicated that students are extensively using GenAI

XSL•FO
RenderX

tools, with ChatGPT usage exceeding 70% [5]. In the face of the widespread adoption of GenAI among students, education must go beyond introducing technological tools. More crucially, we must ensure that future nursing professionals can critically understand, prudently apply, and rationally evaluate AI, thereby transforming technology into a genuine professional enabler [6]. This lays the foundation for nursing students to apply AI tools and technologies appropriately and proficiently.

The American Nurses Association (ANA) asserts that, against the backdrop of emerging AI technologies, nurses applying AI in health care practice require not only ethical guidance but also uphold the core values of care and compassion inherent to nursing [7]. AI literacy (AS) serves as the core competency and vital bridge for integrating ethical guidance and humanistic care into AI application practices. It is regarded as a key competency in nursing education [8]. These capabilities extend beyond merely mastering and applying AI technologies (such as clinical decision support systems and predictive analytics) to encompass the higher-order thinking skills required to independently critically evaluate and assess the outcomes they generate [9]. As the backbone of the future health care system, nursing students are key participants in shaping AI applications in nursing. Their level of AS directly determines whether they can lead the intelligent transformation in this field, thereby profoundly influencing the breadth and depth of their personal career development [10]. Therefore, cultivating AS among nursing students is of paramount importance [11].

However, the cultivation of AS is not an isolated process; it is deeply rooted in the complex psychological, cognitive, and emotional capacity system of individuals [12]. Research indicates that an increasing number of people are turning to GenAI for guidance on interpersonal relationships, self-awareness, and emotional regulation [13]. Emotional intelligence (EI) refers to the ability to recognize, understand, and manage one's own emotions, while also understanding and empathizing with the emotions of others [14]. Higher EI levels are significantly associated with nursing students' stress management, clinical decision-making, and subjective well-being [15]. Research indicates that the use of GenAI can effectively alleviate stress and improve mental health outcomes, while simultaneously enhancing engagement and satisfaction in learning environments [16]. Specifically in the field of nursing education, Ching and Ho [17] found that including AI virtual humans in gamified teaching methods can enhance nursing students' EI. Derakhshan [18] indicates that AI-assisted teaching can enhance students' emotional engagement and goal orientation. Deng and Chen [19] also found that AI-driven environments, by providing personalized feedback and adaptive pathways, enhance their emotional resilience by reducing frustration and boosting students' confidence. These findings collectively reveal that EI not only provides the psychological foundation for students to engage in effective and healthy interactions with AI, but it may also profoundly influence the development and enhancement of their AS by affecting their confidence and initiative when confronting new technologies.
